3.3.6 Beauchamp Methyl, Methylene and Methine Protons

This is a more general method for protons on sp³-hybridized carbons. The method accounts for one or more substituents located within three carbons and uses a different constant for each type of proton. The values used for this method were obtained using substituted methyl, ethyl, propyl, isopropyl, and t-butyl compounds. The deshielding values in Table 26 are used with the appropriate constant in Equation (11):

Methyl (CH₃) protons $\delta = 0.9 \text{ ppm} + \sum \alpha + \sum \beta + \sum \gamma$

Methylene (CH₂) protons $\delta = 1.2 \text{ ppm} + \sum \alpha + \sum \beta + \sum \gamma$

Methine (CH) protons $\delta = 1.5 \text{ ppm} + \sum \alpha + \sum \beta + \sum \gamma$ (11)

A reliability of ±0.5 ppm should be expected when using Equation (11) and Table 26. Table 27 illustrates these calculations for 2-methyl-1-propanol (78-83-1) (8), with experimental data from Aldrich.

3.3 Substituted Alkenes

The calculation of proton chemical shifts for alkenes was studied by Pascual et al. (17) Using Equation (12) and the deshielding values in Table 28 with a data set of 1070 measured chemical shifts, substituent effects were calculated with a standard error of ±0.15 ppm.

$$\delta = 5.28 \text{ ppm} + \sum Z_i$$ (12)

The deshielding effect differs for the substituents in the gem, cis, and trans positions of an alkene (9). The proton chemical shift of ethylene is 5.28 ppm and $Z_i$ is the substituent effect from Table 28 for the position from the proton of interest. Table 29 shows the calculations for the chemical shifts of the alkene protons in ethyl-trans-cinnamate (103-36-6) (10), with experimental data from Aldrich (8).
3.4 Substituted Benzenes

The substituent effects on the proton chemical shifts of benzene are given in Table 30.\(^{(16)}\) These values are used with Equation (13):

\[
\delta = 7.262 \text{ ppm} + \sum \Delta \delta_H
\]  

\((13)\)

According to Martin and Dailey,\(^{(18)}\) the proton chemical shift for ortho disubstituted benzenes is not readily correlated, but for most other substituted benzenes the additivity rules provide accuracies of \(\pm 0.1\) ppm. Table 31 shows the chemical shift calculations for \(p\)-methyl anisole (104-93-8) \((11)\), with experimental results from Aldrich.\(^{(8)}\)

3.5 Cyclic Compounds

Proton chemical shifts given by Pretsch et al.\(^{(4)}\) for a number of cyclic compounds are shown in Figure 4.
is not generally useful. Calculating the chemical shifts for protons on heteroatoms results, these chemical shifts are difficult to predict, and show strong concentration, solvent, and pH effects. As a result, these chemical shifts are difficult to predict, and calculating the chemical shifts for protons on heteroatoms is not generally useful.

3.6 Heteroatoms

Figure 5 is a correlation chart from Silverstein and Webster[10] that shows the expected range for protons on heteroatoms. Many protons on heteroatoms are exchangeable on the NMR timescale and may not be observed in the spectrum. If these protons are observed, wide line widths are common and many chemical shifts show strong concentration, solvent, and pH effects. As a result, these chemical shifts are difficult to predict, and calculating the chemical shifts for protons on heteroatoms is not generally useful.

4 COUPLING CONSTANTS

Although this article does not discuss coupling in NMR spectra, coupling constants are extremely useful in interpreting NMR spectra. Table 32 provides a listing of proton-proton and carbon-proton coupling constants from Pretsch et al.[4]

5 COMPUTER SOFTWARE

Although a detailed review of software is not within the scope of this article, there are software applications that perform many of the calculations discussed here. For routine use, these programs greatly simplify the calculation of chemical shifts. Most of these programs can

**Figure 4** Proton shifts of cyclic compounds.

**Figure 5** Chemical shifts of protons on heteroatoms. (Reproduced by permission of John Wiley & Sons Limited, Copyright 1998, from R. Silverstein, F. Webster, Spectrometric Identification of Organic Compounds, 6th edition, John Wiley & Sons, New York, 1998.)
be divided into one of three distinct categories: chemical shift databases; calculated chemical shifts using additivity rules; and calculated chemical shifts using molecular modeling software.

Comparison with spectral databases is extremely useful for interpreting NMR spectra. The Aldrich NMR Library is available from Advanced Chemistry Development Inc., 133 Richmond Street West, Suite 1501, Toronto, Ontario, Canada M5H 2L3 and the Sadtler NMR Library is available from BioRad, Sadtler Group, 3316 Spring Garden Street, Philadelphia, PA 19104-2596, USA. Both databases are easy to use and contain thousands of experimental spectra. In addition to these two commercial packages, there are also several databases available on the Internet.

There are many software applications that calculate chemical shifts for a structure using databases and additivity rules. These programs include CNMR and HNMR from Advanced Chemistry Development Inc., 133 Richmond Street West, Suite 1501, Toronto, Ontario, Canada M5H 2L3; the C-13 module for ChemWindows from BioRad Sadtler Group, 3316 Spring Garden Street, Philadelphia, PA 19104-2596, USA; Win-SpecEdit from Bruker Instruments Inc., 19 Fortune Drive, Billerica, MA 01821, USA, tel. (508) 667-9580; and ChemDraw Ultra from CambridgeSoft, 100 CambridgePark Drive, Cambridge, MA 02140, USA.

It is also possible to calculate chemical shifts using molecular modeling software. These calculations are computationally very complex but offer the potential of calculating chemical shifts for novel compound classes that are not included in the current databases. These programs include an add-on for HyperChem from Hypercube, Inc., 1115 NW 4th Street, Gainesville, FL 32601, USA and Gaussian98 from Gaussian, Inc., Carnegie Office Park, Building 6, Suite 230, Carnegie, PA 15106, USA.

6 ADDITIONAL INFORMATION

Because the calculation of chemical shifts is so useful for the interpretation of NMR spectra, a considerable amount of information is available. Although this is not a thorough listing, some of the most useful texts are worth noting: the book by Silverstein and Webster is an excellent starting point for information about $^{13}$C and proton ($^1$H) chemical shifts; Pretsch et al. provide an extensive set of tables for calculating chemical shifts of many different compound classes and data for many compounds; and Wehrli et al. and Breitmaier and Voelter provide detailed information about calculating $^{13}$C chemical shifts.

Electron spin resonance (ESR) or Electron paramagnetic resonance (EPR) spectroscopy is an experimental technique for detecting and characterizing chemical systems bearing one or more unpaired electrons. The application of the technique, the background of which is similar to the more diffused nuclear magnetic resonance (NMR) spectroscopy, therefore concerns (i) organic and inorganic free radicals, (ii) trapped radicals in various matrices, including irradiated solids (radiation chemistry), frozen inert matrices and solid surfaces, (iii) transition metal ion compounds in classical inorganic systems or in biological systems, (iv) excited paramagnetic states (triplets) and several other systems of relevant scientific interest. The aim of this article is to provide an overall survey on the basic principles and on the various applications of the technique. This is done by describing, first, the physical basis of the electron resonance phenomenon (microwave absorption when the system is in the line of force of a strong external magnetic field) and, subsequently, the main types of interactions that the unpaired electron undergoes in the chemical system to which it belongs and which determines the features of the experimental spectra. These are essentially (i) the magnetic interaction of the electron with nuclei of nonzero nuclear spin (hyperfine interaction) which determines the multilinear structure of the spectrum (hyperfine structure) and (ii) the interaction of the electron spin with the electron orbital angular momentum, occurring through the so-called spin–orbit coupling. This latter interaction causes the dependence of the resonance on the orientation of the radical in the external magnetic field. Particular emphasis will be given to the different types of spectra observed according to the physical state of the investigated sample (liquid solutions, single solid crystals or microcrystalline powdered solids). In the last case (powders), the essential methodology for understanding the often complex profiles of the experimental spectra is described. Advanced electron resonance techniques, essentially ENDOR (electron–nuclear double resonance) and time-resolved EPR will also be briefly mentioned.

The final part of the article is devoted to some analytical applications of the technique, including spin trapping (an essential tool for the detection and quantitative evaluation of reactive short-lived radicals), radiation dosimetry (with applications to medical problems and irradiated foodstuff analysis) and dating of geologically relevant systems.
1 INTRODUCTION

ESR or EPR is a powerful tool for investigating paramagnetic entities in the domains of chemistry, physics and biology. The limitation of the technique is evident from the previous definition, in that all diamagnetic systems, which represent the majority of the substances, are excluded from EPR investigations. However, this limitation is also an advantage since, for instance, reactive paramagnetic intermediates present in complex media or paramagnetic centers belonging to a complex chemical system (e.g. a paramagnetic ion in a protein) can be studied without any spectroscopic interference.

1.1 Paramagnetism, Unpaired Electrons and Electron Spin Resonance Spectroscopy

Before describing the origin and the concepts of ESR spectroscopy, parts of which are common to the more familiar and widely used NMR, it must be recalled that a paramagnetic body, when placed into the lines of force of a magnetic field, increases the density of the lines of force (called the magnetic flux density) within its own volume. In contrast, a diamagnetic substance decreases the magnetic flux density. Diamagnetism is present in all substances and is produced by electron circulation in atoms, ions and molecules having a closed shell of electrons. Paramagnetism is typical of substances having centers with one or more unpaired electrons and therefore bearing an intrinsic angular momentum – the spin – and a corresponding magnetic moment. These centers are essentially isolated from each other and, consequently, in the absence of magnetic cooperative effects causing ferromagnetism or antiferromagnetism.

In the presence of an external magnetic field, the magnetic moments on different centers tend to align with the field and hence with each other (this effect being contrasted by the randomizing effect of thermal energy), whereas in the absence of a field the unpaired electrons are aligned randomly.

Electron magnetic resonance occurs when an electromagnetic wave of suitable frequency (usually in the microwave region) interacts with the sample immersed in a magnetic field and causes a “flipping over” of the free electron spin vectors, along with the associated magnetic moment, so that a certain amount of electromagnetic energy is absorbed by the system. In quantum mechanical terms the description of the electron resonance (see section 2) can be reduced to the description of the behavior of a single unpaired electron undergoing, under the effect of an external magnetic field, the so-called Zeeman effect, i.e. an energy splitting between the two allowed spin states. Under such conditions an electron in the lower state is promoted to the upper state by absorption of a photon of suitable energy.

Two main features distinguish EPR (and the analogous NMR) from the “classical” types of spectroscopy employing electromagnetic waves to investigate matter. The first is that, in most molecular spectroscopic techniques, the electric-field component of the radiation interacts with some electric dipole moment in the molecules. In magnetic resonance spectroscopy, in contrast, it is the magnetic component of the radiation that interacts with the magnetic dipoles of paramagnetic centers. The second feature concerns the principle of the experimental set-up which, instead of being based on a source of electromagnetic radiation and a monochromator that selects the frequency to be sent to the sample, consists of a source of nearly monochromatic radiation coupled with a variable magnetic field. In a normal experiment with the standard continuous wave electron paramagnetic resonance (CWEPR), the sample is irradiated with a fixed frequency and a given interval of magnetic field is swept to look for the conditions (field and frequency) of the magnetic resonance. A CWEPR spectrum is thus a diagram where microwave absorption (or more frequently, for the reasons discussed in section 2, its first derivative) is reported as a function of the magnetic field swept in the experiment.

1.2 Origin of the Technique and Applications in Chemistry

The first observation of an EPR spectrum was made in Kazan (USSR) in 1945 by Zavoisky. The technique was, however, developed mostly at Oxford (UK) from both theoretical (Pryce, Abragam) and experimental (Bleaney) points of view, and also on the foundations provided by earlier work by Van Vleck on magnetic susceptibility. A considerable contribution to the exploitation of the EPR technique was due to the development of microwave systems, to be employed for radio detection and ranging (radar), during the Second World War. The first applications of EPR to chemistry were in the field of transition metal ions, and the observations on the spectra of organic radicals were performed later in 1952.

To classify the applications of EPR in chemistry, physics and biology it is convenient to have in mind a clear methodological distinction. EPR is employed according to two basic approaches. In the first, paramagnetic entities are introduced in diamagnetic, usually complex, systems to obtain information on the properties of the systems themselves. This technique is usually termed the “spin-probe” or “spin-label” method. In the former case, the probes, usually paramagnetic ions or stable nitroxide radicals, are added to complex systems such as biological
membranes to “explore” particular structural features or alterations of the properties caused by pathologies, interactions with drugs, etc. The spin label is also a stable radical like a nitroxide but it has a particular functional group suitable to bind the molecule permanently to particular sites of the system. For its high specificity the spin-probe–spin-label method will not be discussed further in this article.

In the second approach, EPR directly investigates paramagnetic centers present in various chemical and biological systems. Typical systems that are studied in EPR include

- Free radicals in chemistry, biochemistry and biology.
- Radicals and paramagnetic point defects trapped in solid matrix. EPR, in fact, is one of the leading techniques to study the effects of radiation in the solid state and, generally, for the study of defects in solid state physics and material science.
- Transition metal ion compounds in inorganic chemistry and bioinorganic chemistry.
- Systems with more than one unpaired electron (triplets, quadruplets, etc.). Some of these systems are stable ground states but, in most cases, they are excited short-lived states.

Several new specific applications of EPR have recently appeared which are aimed at solving particular problems in branches of science other than chemistry, physics and biology. This is the case, for instance, with dating techniques in archaeology and geology and with nuclear radiation dosimetry. These recent applications of EPR will be described in section 6.

The classical CWEPR is by far the most commonly used electron magnetic resonance technique. For this reason, this article mainly refers to this experimental approach. However, the constant evolution of the microwave physics and engineering has allowed the introduction of new experimental approaches in the field of electron magnetic resonance. The first and probably the most important one is the ENDOR, introduced in the late 1950s, which will be briefly described in section 5.2.

In conclusion to these introductory remarks, it should be pointed out that whether or not the reader has an immediate interest in the multitude of physical systems that can be investigated by EPR, this type of spectroscopy occupies a paramount position among the many physical techniques employed to investigate matter. In fact, there are hardly any other techniques that provide such a deep and detailed insight into the investigated systems. Furthermore, the quantum mechanics concepts that are needed for a nontrivial understanding of the principles and of the results of EPR have made this technique a stimulating intellectual challenge for many researchers in various domains of science.

1.3 Books and Chapters About Electron Spin Resonance Spectroscopy

The content of this article is basically a short introduction to the basic principles and applications of ESR. The reader wishing to increase their level of knowledge on this subject is referred to a series of modern general books covering all the basic aspects of the technique. The particular domain of transition metal ions is well covered by several books, as are the domains of spin labeling and biological applications of EPR. Modern double-resonance and pulsed techniques, which are assuming increasing importance in the field of electron magnetic resonance, are illustrated in several books and review articles and an interesting report on new applications of EPR to fields such as dating and radiation dosimetry has also appeared recently.

2 BASIC PRINCIPLE OF THE TECHNIQUE

2.1 Electron Spin and the Zeeman Effect

The fundamental properties of an electron are mass, charge and intrinsic angular momentum or spin, a vector denoted by the symbol \( \mathbf{S} \). It is known from quantum mechanics that only the square of the intrinsic angular momentum (\( S^2 \)) and one component in a given direction (say \( z \), hence \( S_z \)) can be measured with certainty. The intrinsic angular momentum of a given quantum system is defined by the spin quantum number \( S \), which can assume integer or half-integer values only (0, \( \frac{1}{2} \), 1, etc.). For an electron \( S = \frac{1}{2} \). As a consequence, the allowed \( S_z \) values are two (\( 2S + 1 \) are the allowed values), i.e. \( S_z = \pm \frac{1}{2} \) (sometimes referred to as the \( \uparrow \) or \( \downarrow \) state, quantum number \( M_z = \pm \frac{1}{2} \), \( S_z = -\frac{1}{2} \) (\( \downarrow \) or \( \beta \), \( M_z = -\frac{1}{2} \)). The symbol \( h \) represents the unit of angular momentum, \( h = h/2\pi \), where \( h \) is Planck’s constant, \( h = 6.626 \times 10^{-34} \text{ J s} \). \( S^2 \) in general is \( S(S + 1)h^2 \) and becomes, for an electron, \( S^2 = \frac{1}{4}h^2 \) with \( S = \frac{1}{2}h \) (Figure 1).

The electron, by virtue of its spin, has associated with it a magnetic moment \( \mu \), which is collinear and antiparallel
randomly aligned, but in the presence of an external magnetic moment) of an assembly of free electrons are respectively, and

\[ g_a \]

a magnetic field the spin vectors

where

\[ g \]

electron charge and mass, \( c \) the velocity of light. In the absence of a magnetic field the spin vectors \( S \) (and the corresponding magnetic moments) of an assembly of free electrons are randomly aligned, but in the presence of an external magnetic field the magnetic moments tend to align and define the axis of orientation of the \( S_z \) component. The situation is illustrated in Figure 1. Because of the complete uncertainty with respect to the \( S_z \) and \( S_y \) components, the vectors representing the spin of the electrons can lie on the surface of one of the two cones whose axes coincide with the \( z \) axis. In this way all electrons assume one of the two permitted \( S_z \) values (\( +\frac{1}{2} \hbar, -\frac{1}{2} \hbar \)). It is known from classical physics that an energy develops by interaction between a magnetic field and a magnetic dipole having a given magnetic moment \( \mu \) which is given by a scalar product (Equation 2):

\[ E = -\mu B \]

[where \( B \) is the magnetic flux density in the matter measured in tesla (T) or gauss (G) (1 T = 10^4 G)] and which thus depends on the orientation of the magnetic dipole with the field \( (E = \mu B \cos \theta) \). This means that for electrons in a magnetic field, the two permitted orientations of the spins (\( \alpha \) and \( \beta \)) have different energies. In a field of 3000 G, for instance, the \( \alpha \) state lies 0.3 cm\(^{-1} \) above the \( \beta \) state. This phenomenon is sometimes called the electronic Zeeman effect, or the first-order Zeeman effect. In quantum mechanics, the \( \mu \) vector in Equation (2) is replaced by the corresponding operator (Equation 1) leading to the Hamiltonian in Equation (3), i.e. the energy operator:

\[ H = g_s \mu_B BS \]

As \( B \) lies along the \( z \)-axis \( (B_z = B, B = B_z) \), we have (Equation 4)

\[ H = g_s \mu_B B \hat{S}_z \]

which is the simplest example of a spin Hamiltonian, i.e. the energy operator acting on the spin components of the whole electron wave function. \( \hat{S}_z \) acts on the spin functions \( \alpha \) and \( \beta \) according to

\[ \hat{S}_z | \alpha \rangle = \frac{1}{2} | \alpha \rangle \quad \text{and} \quad \hat{S}_z | \beta \rangle = -\frac{1}{2} | \beta \rangle \]

The permitted energy levels of the system (i.e. the energies corresponding to the two allowed orientations of the spin) are therefore

\[ E = \left( \pm \frac{1}{2} \right) g_s \mu_B B \]

The lower energy state occurs when the electron magnetic moment is lined up with the applied magnetic field \( (M_s = +\frac{1}{2}, \beta) \). A higher energy state occurs when \( \mu_s \) lines up in opposition to the magnetic field \( (M_s = -\frac{1}{2}, \alpha) \). The energy difference between these two states is given by Equation (6):

\[ \Delta E = g_s \mu_B B \]

At thermal equilibrium, under the influence of the external applied magnetic field, the spin population is split between the two levels according to the Maxwell–Boltzmann law (Equation 7):

\[ \frac{n_\alpha}{n_\beta} = e^{\frac{-\Delta E}{kT}} \]

where \( k \) is Boltzmann’s constant, \( T \) the absolute temperature and \( n_\alpha \) and \( n_\beta \) are the spin populations characterized by the \( M_s \) values \(+\frac{1}{2}\) and \(-\frac{1}{2}\) respectively. At 77 K, in a field of about 3000 G, \( n_1 \) and \( n_2 \) differ by less than 0.005.

**Figure 1** The two possible orientations of the spin of a free electron in a magnetic field oriented along the \( z \)-axis.
2.2 Spin Resonance and Spin Relaxation

The ESR experiment is the observation of the energy required to reverse the direction of an electron spin in the presence of an external magnetic field. Electrons in the lower Zeeman state (β) can be promoted to the upper state (α) by irradiating the paramagnetic system with suitable electromagnetic radiation. To observe the spin transition the following condition (Equation (8)) must be fulfilled:

$$h\nu = g_e \mu_B B$$  \hspace{1cm} (8)

From Equation (8), it can easily be deduced that for a free electron in a 3000-G magnetic field the resonance frequency υ lies in the microwave region of the electromagnetic spectrum (~9 GHz). However, for reasons that will be explained in section 2.3, the actual EPR experiment is run by irradiating the sample with a fixed frequency and sweeping a suitable range of magnetic field. When the magnetic field reaches the value necessary to fulfill the resonance condition in Equation (8) (which is also called the resonant field), an absorption of energy is observed that results in a spectral line. The width of this line (reported in Figure 2 both as absorption and first derivative of absorption) essentially depends on the efficiency of the mechanism (relaxation mechanism) through which the excited system returns to the ground state.

By the absorption process, in fact, the populations of the two energy levels \(n_a\) and \(n_b\) tend to equalize. The odd electrons from the upper level give up an amount of energy corresponding to the \(h\nu\) quantum to return to the lower level in order to satisfy the Maxwell–Boltzmann law. This energy may be dissipated in two different types of relaxation processes, spin–lattice and spin–spin relaxation, respectively. In the former mechanism, the magnetic energy absorbed by the paramagnetic system is transferred to vibrational degrees of freedom of the lattice. The motions of the lattice (phonons) give rise to fluctuating magnetic fields at the unpaired electron; if these fluctuations happen to have a component that oscillates at the transition frequency, then a transition can be induced. The width of the resonance line is inversely proportional to the lifetime of the excited state. This can be shown in terms of Heisenberg’s uncertainty principle, which relates the line width to the lifetime of the excited state, by Equation (9):

$$\Delta t \Delta E \approx \frac{h}{2\pi}$$  \hspace{1cm} (9)

where \(\Delta t\) is the lifetime of the excited state and \(\Delta E\) the effective width of the energy band involved. From Equation (9), it immediately follows that if \(\Delta t\) is small, \(\Delta E\) will be large and the absorption will be observed over a range of energies (or magnetic field) corresponding to a large line width. Spin–lattice relaxation is characterized by an exponential decay of energy as a function of time. The exponential time constant is denoted \(T_1\) or spin–lattice relaxation time. \(T_1\) has been found to be sensitive in particular to

- Temperature. A decrease in temperature decreases the population of phonons and leads to a longer relaxation time and correspondingly narrower lines.
- The presence of nearby electronic excited states. Where these are close (~100 cm\(^{-1}\)) to the ground state, the relaxation time will be very short and the line width very large or even not observable.

The other relaxation process that may take place is the spin–spin relaxation process. This phenomenon is characterized by a time constant \(T_2\) called the spin–spin relaxation time and involves an energy exchange between the electron spins without transfer of energy to the lattice. The width and the shape of the EPR lines are strictly related to the type and to the rate of the motion that a given paramagnetic center undergoes. An important application of EPR is the study of the motional behavior of particularly stable radicals in various media (e.g. natural and artificial membranes, liquid crystals) to obtain information on the whole system. The radical molecules employed in these kinds of studies are usually nitroxides (containing an –NO\(^+\) group) and are called spin probes or spin labels.

When a spin system is irradiated with a microwave power too high for the efficiency of the relaxation mechanism operating in the system itself, the populations of the two Zeeman levels tend to equalize and the intensity of the signal decreases, no longer being proportional to the number of spins present in the sample. This effect, known as “saturation”, can be avoided by exposing the sample to suitable microwave power. In

![Figure 2](image-url)  
**Figure 2** The electron Zeeman effect. The energy difference between the α and β spin states is proportional to the value of the applied magnetic field.
order to determine the microwave power that avoids saturation effects, the signal intensity is usually plotted as a function of the square root of the incident microwave power. Three examples of such a plot are shown in Figure 3.

The linear part of the plot indicates the power region where saturation effects are absent. Three different saturation trends can therefore be identified: (A) no saturation of the signal; (B) homogeneous saturation, typical of single EPR lines arising from a single EPR parameter and from samples exhibiting a single type of center or, at least, little heterogeneity of the centers; and (C) heterogeneous saturation, occurring when the EPR lines arise from the superimposition of several overlapping individual lines. The saturation of an EPR spectrum is sometimes employed in heterogeneous systems, or systems containing more than one type of paramagnetic species, in order to increase the intensity of one resonance with respect to a second partially overlapped signal.

When both spin–lattice and spin–spin relaxations contribute to the EPR line, a rough expression of the resonance line width is (Equation 10):

$$\Delta H \propto \frac{1}{T_1} + \frac{1}{T_2}$$

(10)

In general $T_1 > T_2$ and the line width depends mainly on spin–spin interactions: $T_2$ increases on decreasing the spin concentration, i.e. the spin–spin distances in the system.

There are two typical line shapes that are useful to describe the EPR lines, namely Gaussian and Lorentzian, whose analytical expressions are given by Equations (11) and (12), respectively:

$$y = ae^{-b\gamma^2}$$

$$y = \frac{a}{1 - b\alpha^2}$$

(11)

(12)

A detailed description of the line shape in EPR is beyond the scope of this article. It is sufficient to note that the Gaussian line shape occurs in magnetic resonance from the statistical distribution of similar paramagnetic centers.

2.3 The Continuous Wave Electron Paramagnetic Resonance Spectrometer

A CWEPR spectrometer is designed to detect with high sensitivity the microwave absorption in a sample as a function of the external applied magnetic field. The EPR experiment is performed by maintaining a constant microwave frequency and sweeping the applied field until the resonance condition, given by Equation (8), is fulfilled, i.e. the incident radiation is absorbed.

The basic components of the spectrometer (Figure 4) are as follows:

![Figure 4 Scheme of a CWEPR spectrometer.](image-url)

- A microwave source (klystron or Gunn diode) supplying electromagnetic radiation at a constant frequency $\nu$ whose power is controlled by an attenuator between the microwave source and the sample. The frequencies most often employed are those corresponding to X ($\sim$9 GHz) and Q ($\sim$35 GHz) bands. In the second half of the 1990s, the high-frequency W band (96 GHz) became commercially available. Other frequencies, e.g. K (25 GHz) and S (3 GHz) band, are sometimes employed. The experimental features of these bands are reported in Table 1.

- A microwave guide system to direct the microwave radiation from the source to the resonant cavity.

- A cavity made from a highly conductive metal and having reflecting walls to accumulate power of the microwave radiation on to the sample. The internal dimensions of the cavity are similar to the wavelength of the microwaves.

- A powerful electromagnet capable of providing a homogeneous field that is controlled by a field probe. The rate and range of scanning are adjusted to provide the most suitable conditions for observation of the microwave absorption.

- A detector diode to measure the energy absorbed by the sample at resonance.

- A convenient amplifier system, a recorder, and an oscilloscope.

Superimposed on the main magnetic field, an oscillating field is obtained by applying an alternating current (typically 100 kHz) to a set of coils in the cavity walls. This modulating field converts the resonance to an alternating signal, which can be separated from random noise using a phase-sensitive detection system. This method of detection has a very high sensitivity and leads to an output whose amplitude is proportional to the slope $A_1$ and $A_2$, so that the resulting EPR signal now appears as the first-derivative curve, i.e. to prevent distortions, which occur if the value of the amplitude approaches the resonance line width.

First-derivative curve, i.e. to prevent distortions, which occur if the value of the amplitude approaches the resonance line width.

Paramagnetic compounds are usually studied by EPR either in solution or in the solid state. In the solid state one has to distinguish between single-crystal systems and polycrystalline systems. The latter case encompasses the true polycrystalline solids (powders) and the frozen solutions.

2.3.1 Fluid Solution

Samples of stable paramagnetic compounds in fluid solution are usually easy to prepare. The removal of oxygen (which is a paramagnetic $S \neq 1$ molecule) from the solvent is sometimes necessary in order to obtain narrower resonance lines. In certain cases (e.g. unstable radicals) it is possible to generate the radicals in situ in the EPR cavity. The usual sample tubes used for the EPR experiment are cylindrical tubes made of quartz glass, since Pyrex and other glasses contain small traces of paramagnetic impurities. It is also essential to expose only a thin sample to the microwave radiation, since all solvents absorb the microwaves to various degrees and if much absorption occurs it is not possible to obtain resonance. Good solvents are those that cause the minimum absorption effects and, in general, these are characterized by having low permittivity (dielectric constant). In the case of aqueous solutions (water has a high dielectric constant), special flat cells are usually employed, in which a liquid layer of about 0.1 mm is present. These undesirable effects of high dielectric constant solvents are strongly reduced in the solid state.
2.3.2 Single Crystal

Magnetically dilute single crystals of a paramagnetic compound can be obtained by growing a crystal of an isomorphous diamagnetic compound containing the paramagnetic species as impurity. Any of the standard crystal-growing methods may be used, the choice depending on the nature of the radical being studied. Alternatively, a single crystal containing a paramagnetic impurity may be produced by means of high-energy radiation of the bare crystal. As will be shown below, the EPR spectra of single crystals exhibit different features as a function of the orientation of the sample in the cavity (anisotropy of magnetic tensors).

2.3.3 Powders, Glasses and Frozen Solutions

The EPR spectra of polycrystalline materials exhibit different features from those of single crystals, since they are invariant to rotation of the sample in the cavity (see below). Polycrystalline materials can be either assemblies of very small single crystals randomly oriented in the space or microcrystals of a frozen solution. In fact, a convenient method for the study of many compounds is to observe their EPR spectra in solution and then to freeze the solution and observe the solid-state spectrum. The former spectra give the isotropic parameters for the various species, while the latter yield the anisotropic data. A particular case is glasses and amorphous materials which, from the point of view of EPR, display the same spectral features as a polycrystalline material.

Low-temperature EPR spectra can be recorded at 77 K using a special Dewar fitting in to the cavity. Variable-temperature EPR spectra can be recorded by using a flow of cooled, dried nitrogen in a liquid nitrogen cryostat for temperatures from about 120–130 K up to 450 K. A flow of cooled, dried helium in a liquid helium cryostat allows spectra to be recorded from 4 K. Both nitrogen and helium cryostats are fitted into the EPR microwave cavity.

The digital acquisition of spectra with on-line computers (which are included in modern spectrometers) allows an improvement of the signal-to-noise ratio by both spectra accumulation and spectral curve smoothing. Mathematical data handling can be also used to obtain second and third derivatives of the spectra, which are extremely useful for detecting overlapping signals. The measurement of spin concentration is done by double integration of the first-derivative EPR signal and comparison of the intensity of the integrated signal (which is proportional to the number of spins present in the system) with that of standard samples with a known number of spins.

3 SPIN RESONANCE IN ATOMIC AND MOLECULAR SYSTEMS

To understand how information about the nature and the structure of a real paramagnetic entity is obtained by means of EPR, we now have to consider how the unpaired electron interacts with its environment. The interactions of an unpaired electron with its surroundings (in addition to the Zeeman interaction with the external magnetic field) are essentially of magnetic or electric nature. We shall limit ourselves in this section to a purely phenomenological approach, considering the three main interactions potentially involving an unpaired electron. These are (i) the electron spin–nuclear spin interaction (hyperfine interaction), (ii) the coupling of the spin angular momentum with angular momenta of orbital origin and (iii) the interaction of the electron spin with other electron spins. An unpaired electron in a real chemical system does not necessarily undergo all these three types of physical interactions. It will be shown in the following, for instance, that the spectra of organic radicals in solution are mainly analyzed in terms of the electron spin–nuclear spin coupling. It will also be clarified in this section that the main problems in the analysis of experimental EPR spectra arise because of the anisotropic nature of all the above-mentioned magnetic interactions. This means that the extent of such interactions varies as a function of the orientation of the sample in the external magnetic field. The anisotropic effects show up for samples in the solid state, but are averaged (and, in some cases, vanish) for paramagnetic systems in low-viscosity solutions because of the rapid molecular motion.

3.1 The Electron Spin–Nuclear Spin (Hyperfine) Interaction

Most of the information which can be deduced from EPR spectra arises from the analysis of the hyperfine structure. This is particularly true for organic radicals which exhibit small $g$ shifts (the other parameter characterizing EPR spectra and better observed in high-frequency Q or W bands rather than in the classical X-band) which, in any case, are not easy to correlate with the molecular structure.

A hyperfine structure is composed of a series of lines with different intensity and well-defined separation which arise from the interactions between electron and nuclear magnetic dipoles in the case of nuclei with nonzero nuclear spin. The case of a free radical with a single nucleus of spin $I = \frac{1}{2}$ will be discussed in some detail and the most important results will be extended to the case of interactions with $n$ nuclei.

Several nuclei possess spins and associated magnetic moments. The magnetic moment $\mu_n$ associated with a
nucleus is collinear with the spin vector $I$ according to Equation (13):
\[ \mu_n = g_n \beta_n I \]  
where $g_n$ is the nuclear $g$ factor and $\beta_n$ is the nuclear magneton ($\beta_n = 5.05 \times 10^{-27} \text{ JT}^{-1}$), which is the analog of the Bohr magneton for the proton mass. Nuclear and Bohr magnetons are correlated by a factor of 1838, i.e., the ratio between the proton and electron masses.

For a nucleus with nuclear spin $I = \frac{1}{2}$ the interaction of the nuclear magnetic moment with an external applied magnetic field can be described in terms of the following Hamiltonian (Equation 14):
\[ H = -g_n \beta_n \mathbf{B} \cdot \mathbf{I} \]  
(14)
If $\mathbf{B}$ lies in the $z$ direction ($B_x = B_y = 0$ and $B_z = B$), the interaction energy corresponds to (Equation 15)
\[ H = -g_n \beta_n \mathbf{B} \cdot \mathbf{I}_z \]  
(15)
and the energy corresponding to the two allowed orientations of the nuclear spin (nuclear Zeeman effect) is given by Equation (16):
\[ E = (\pm \frac{1}{2}) g_n \beta_n B \]  
(16)
The total spin-Hamiltonian for the case under discussion is composed of three terms and can be written according to Equation (17):
\[ H = g_{\text{iso}} B \mathbf{S} - g_n \beta_n B_z \mathbf{I}_z + a \mathbf{I} \mathbf{S} \]  
(17)
The first and second terms account for the electron–Zee- 
man (Equation 4) and nuclear–Zeeman (Equation 15) interactions respectively, which have been discussed above. The third term accounts for the electron spin–nuclear spin interaction (i.e., hyperfine interaction) and $a$ is called the hyperfine splitting constant. This interaction originates from the fact that, with the electron and the nucleus being two magnetic dipoles situated in close proximity to one another, they undergo a reciprocal interaction.

Two types of electron spin–nuclear spin interactions must be considered depending on whether the electron interacting with the nucleus is in an $s$ or in any other orbital of higher $l$ (e.g., $p$, $d$ and $f$ orbitals). In the first case the interaction is called the isotropic hyperfine coupling or Fermi contact interaction and is related to the finite probability of the unpaired electron being at the nucleus. For odd electrons in $p$, $d$ or $f$ orbitals no Fermi contact occurs due to the nodes of the corresponding wave functions at the nucleus. The electron spin–nuclear spin interaction is in this case due to the nonspherical symmetry of the orbitals and can be described in terms of the classical dipolar interaction between magnetic moments. The interaction is anisotropic in that it depends on the orientation of the orbital with respect to the applied magnetic field.

### 3.1.1 Anisotropic Hyperfine Interaction

The interaction energy between two magnetic moments ($\mu_1$ and $\mu_2$) is classically given by Equation (18):
\[ E = \frac{\mu_1 \mu_2}{r^3} - \frac{3(\mu_1 r)(\mu_2 r)}{r^5} \]  
(18)
where $r$ is the vector relating the two moments and $r$ is the distance between them. The quantum mechanical analog of Equation (18) is obtained by replacing $\mu_1$ and $\mu_2$ by their corresponding operators (Equation 19):
\[ H_{an} = -g_m \mu_B g_n \beta_n \frac{\mathbf{I} \mathbf{S}}{r^3} - \frac{3(\mathbf{I} \cdot \mathbf{r})(\mathbf{S} \cdot \mathbf{r})}{r^5} \]  
(19)
Since the electron is not localized at one position in space, Equation (19) must be averaged over the electron probability distribution function. $H_{an}$ is averaged out to zero when the electron cloud is spherical ($s$ orbital) and comes to a finite value in the case of axially symmetric orbitals ($p$, $d$, etc.).

### 3.1.2 Isotropic Hyperfine Interaction

We now turn to consider the situation when the electron is in an $s$-type orbital. The simplest example of isotropic hyperfine interaction is the one observed for the hydrogen atom. The classical dipolar interaction cannot account for the hyperfine splitting in the hydrogen atom (whose EPR spectrum is constituted by two lines separated by about 508 G) since the electron distribution in a $1s$ orbital is spherically symmetric. The dipolar interaction is thus averaged to zero.

As mentioned above, the isotropic hyperfine interaction is related to the unpaired electron density at the interacting nucleus which has a nonzero value for $s$-type orbitals. The spherical symmetry of $s$ orbitals explains the isotropic nature of the contact interaction, which is also known as the Fermi contact interaction and is given by Equation (20):
\[ a = a_{\text{iso}} = \frac{8\pi}{3} g_e g_m \mu_B \beta_n |\langle \Psi_0 | \rangle|^2 \]  
(20)
where $|\langle \Psi_0 | \rangle|^2$ is the square of the value of the wave function of the unpaired electron evaluated in the volume of the nucleus.

Let us now tackle the example of an unpaired electron spin interacting with the proton ($I = \frac{1}{2}$) spin. The interaction occurs via isotropic Fermi contact only. The case of a hydrogen atom corresponds to the schemes proposed in this example which is, however, rather
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 6 Energy levels scheme for the case of an unpaired electron \( (S = \frac{1}{2}) \) interacting with one nucleus having nuclear spin \( I = \frac{1}{2} \). The scheme corresponds to the case of the hydrogen atom. The observed spin transitions are evidenced and the related EPR spectrum is shown.

The scheme in Figure 6 and the energy differences (Equations 21 and 22) have been conceived for practical reasons for a virtual CWEPR experiment at constant \( B \) and variable microwave frequency. In these terms the two allowed transitions are separated by the hyperfine splitting constant, expressed in energy units (Equation 23):

\[
hv_1 - hv_2 = a \quad (23)
\]

In a real CWEPR experiment (sweeping magnetic field at constant \( \nu \)), the two transitions take place at two different \( B \) values \( (B_1 \) and \( B_2 \)) separated by \( a' = a / g \mu_B \) (in magnetic field units (Equation 6)). As already mentioned, the EPR spectrum of the hydrogen atom is composed of two lines split by approximately 508 G (Figure 6).
The Fermi contact interaction is not the only effect which contributes to the isotropic hyperfine coupling. Since isotropic coupling is associated with unpaired electron spin density at the nucleus, then transition metal ions with unpaired electrons in d orbitals would not be expected to exhibit any isotropic coupling. However, appreciable isotropic coupling is always observed, e.g. vanadyl (VO$^{2+}$) complexes have $\mu_{ct}^{(51V)}$ values of up to nearly 120 G.

Another example is constituted by aromatic radicals such as C$_6$H$_6^-$. In this case the unpaired electron is located in a π molecular orbital formed from the overlap of carbon 2p$_z$ orbitals. This molecular orbital has a node in the molecular plane containing the protons which give rise to the hyperfine structure. Also, in this case, the question is how the s orbitals of the hydrogen atoms can share a finite spin density to account for the observed hydrogen hyperfine structure.

In both cases a mechanism of spin polarization acts. This is described in terms of an exchange interaction between the unpaired electron and the paired s electrons. In the case of an odd electron in d orbitals, for example, spin polarization will occur between the unpaired d electron and the paired s electrons.

This is described in terms of an exchange interaction (Equation 25):

$$H = g\mu_B BS + \sum_j IAS + \sum_j g_n\beta_n BI$$

where $A$ represents the total hyperfine tensor. The third term expresses the nuclear Zeeman interaction which is included for the sake of completeness but, as already shown, does not influence the energy of the transitions.

The $A$ tensor may be split into the isotropic and anisotropic parts as follows (Equation 25):

$$A = \begin{pmatrix} 0 & 0 & 0 \\ 0 & A_2 & 0 \\ 0 & 0 & A_3 \end{pmatrix}$$

with $a_{iso} = (A_1 + A_2 + A_3)/3$. The anisotropic part of the A tensor corresponds to the dipolar interaction as expressed by the Hamiltonian in Equation (19). In a number of cases, the second term matrix of Equation (25) is a traceless tensor ($T_1 + T_2 + T_3 = 0$) and has the form $(-T, -T, +2T)$. For this reason in the case of EPR spectra of paramagnetic species having both isotropic and anisotropic hyperfine coupling and undergoing rapid tumbling in a low-viscosity solution, the anisotropic term is averaged to zero and the observed hyperfine coupling corresponds to the isotropic part only ($a_{iso}$). Extremely useful information derived from the hyperfine structure of an EPR spectrum are the s and p characters of the orbital hosting the unpaired electron [or, in other words, the coefficient of the atomic wave functions involved in the semi-occupied molecular orbital (SOMO)]. These data can be deduced from Equations (26) and (27):

$$C_s^2 = \frac{a_{iso}}{A_0}$$

$$C_p^2 = \frac{T}{B_0}$$

where $A_0$ and $B_0$ are experimental or, more frequently, theoretical hyperfine coupling constants assuming pure spin.
s and p orbitals for the element under consideration and \( C_s^2 + C_p^2 + \cdots = 1 \). For instance, the \( A_2 \) value for hydrogen is, in magnetic field units, 508 G.

### 3.2 Organic Radicals in Solution

As shown before for the EPR spectrum of the hydrogen atom, the effect of the hyperfine interaction with a single nucleus of \( I = \frac{1}{2} \) is to split each electron energy level into two. In the general case, if the nuclear spin is \( I \), then \( 2I + 1 \) energy levels are present. Free organic radicals usually contain several nuclei having nuclear spin \( I \neq 0 \) (also called magnetic nuclei). The spectra of organic radicals in solution can be discussed in the same terms as those adopted for the H atom. This is because (1) the influence of the orbital momenta on the electron spin is negligible (see section 3.3) and the \( g \) value of organic radicals is close to the free electron value \( (g_e) \) and (2) the hyperfine interaction is reduced to the isotropic Fermi contact term in the H atom (Figure 6), is obviously schematic. The interaction of the unpaired electron with the first nucleus causes the \( a/2 \) splitting of the two Zeeman electron levels. The interaction with the second nucleus causes each level to be split again by \( a/2 \) as magnetic equivalence implies that hyperfine splitting constants are identical. It is worth noting that in both \( M_s = -\frac{1}{2} \) and \( M_s = -\frac{1}{2} \) (or \( \alpha_e \) and \( \beta_e \) groups), there is a twofold degeneracy of the levels with \( M_l = 0 \) associated with the two possible permutations of two nuclear spins giving rise to a zero net spin \( \left( \alpha_2 \beta_2 \right) \). This degeneracy is reflected in the 1:2:1 trend of the spectral intensities (Figure 8b). The three lines are separated by \( a \), which is the value of the hyperfine coupling constant. In the general case for \( n \) equivalent nuclei with \( I = \frac{1}{2} \), the degeneracies are just the coefficients in the binomial expansion of \( (1 + x)^n \), which can readily be found from Pascal’s triangle (Figure 9a).

In order to depict this situation visually a collection of simulated spectra of radicals containing up to eight equivalent protons, all having the same coupling constant \( a \), is presented in Figure 9(b).

In a large variety of cases one is dealing with radicals containing magnetically inequivalent protons. These in general exhibit different hyperfine splitting constants. The case of two inequivalent protons with hyperfine coupling constants \( |a_1| > |a_2| \) is considered. A schematic energy-level diagram may be built up by considering firstly the \( a_1/2 \) hyperfine splitting due to the first proton and then each of these two levels to be split into two new levels separated by \( a_2/2 \). The scheme is shown, along with the corresponding EPR spectrum, in Figure 10(a) and (b).

The situation becomes much more complex when different sets of magnetically equivalent nuclei are present. In these cases the interpretation of the spectrum may not be straightforward, and isotopic labeling and computer simulation of the spectrum or double-resonance experiments, such as ENDOR, are sometimes necessary in order to assign successfully the large number of hyperfine lines. A beautiful example of such complexity is provided by the EPR spectrum of the radical cation \([1.1.1.1]\text{pagodane}\) \(^{(18)}\) the structure of which is shown in Figure 11(a).
Figure 9 (a) Practical scheme to calculate the relative intensities of the EPR lines for organic radicals having a given number \( n \) of equivalent protons. The intensities are the coefficients of the binomial expansion \( \binom{n}{x/n} \). (b) Calculated spectra for organic radicals having from two to eight equivalent protons.

Figure 10 (a) Energy levels scheme for the case of an unpaired electron \( (S = \frac{1}{2}) \) interacting with two nonequivalent hydrogen atoms \( (I = \frac{1}{2}) \). The observed spin transitions are evidenced and the related EPR spectrum is shown in (b).

The magnetic moment of an electron due to its spin angular momentum given in Equation (1) is given by Equation (28):

\[
\mu_s = -g_e \mu_B S
\]  

where \( g_e \) is a dimensionless factor to which experiments ascribe the value 2.0023. If the magnitude of the magnetic moment associated with each unpaired electron in a paramagnetic system had this same value, then all resonances would be expected to occur at the same field in a spectrometer operating at frequency \( \nu \) according to the resonance condition (Equation 29):

\[
B_{\text{res}} = \frac{\nu}{g_e \mu_B}
\]

However, in most experimental cases, the resonant field \( B_{\text{exp}} \) observed for a given signal determines a value for \( g \) (Equation 30):

\[
g = \frac{\nu}{B_{\text{exp}} \mu_B}
\]

which is different from \( g_e \) and which is called the \( g \) factor. The difference between \( g \) and \( g_e \) is very small for free radicals but can be significant in the case of paramagnetic transition metal ions. To explain the origin of the \( g \) factor we have to consider the interaction between the unpaired electron and its environment. In particular, since the electron belongs to an orbital associated with the paramagnetic species, the interaction occurring between the spin \( S \) and the angular orbital momentum \( L \) must now be considered if the latter is different from zero.
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

This interaction causes a deviation of the g value from 2.0023. Actually, for a series of reasons related to the electric fields present in molecules and solid systems, the orbital angular momentum \( L \) is quenched and its contribution to the total angular momentum should be zero in most cases and not only for \( S \) states (i.e. those states for which \( L = 0 \)). However, \( L \) is partially restored by a magnetic interaction that operates via an admixture of excited electronic states to the ground state. This interaction is called the spin–orbit coupling. The role of the partially restored \( L \) in the system containing the unpaired electron can be visualized by making the electron itself (which is orbiting a nucleus of charge \( Z_e \)) the origin of the coordinate system. In these terms the electron sees a positive charge moving about it and, as a result of this positive current, a magnetic moment originates at the electron position. This means that the electron spin magnetic moment interacts with a local magnetic field arising from its own orbital motion which, in the EPR experiment, is added to the external field. The true magnetic field experienced by the electron thus differs from the applied field.

The energy of the spin–orbit interaction is approximately given by the Hamiltonian (Equation 31):

\[
H_{\text{s-o}} = \lambda LS
\]  

(31)

where \( \lambda \) is the spin–orbit coupling constant, which depends strongly on the atomic number \( Z \) of the atom. The strength of the spin–orbit interaction increases with increasing \( Z \). The value of \( \lambda \) can be estimated experimentally from the fine structure of atomic spectra. The whole spin Hamiltonian for a \( S = \frac{1}{2} \) nondegenerate electronic ground state with zero nuclear moments exclusively (\( \mu_n = 0 \)) can thus be written according to Equation (32):

\[
H = g_s \mu_B BS + \mu_B BL + \lambda LS
\]  

(32)

where the second term accounts for the energy of the interaction between the orbital angular momentum \( L \) and the external field (orbital Zeeman interaction). The previous Hamiltonian reduces to (Equation 33):

\[
H = \mu_B gS
\]  

(33)

where \( g \) is now a symmetric (3 \( \times \) 3) matrix (or a second-rank tensor), indicating that the Zeeman interaction is anisotropic. The described transformation of the scalar \( g_e \) value (2.0023) into a \( g \) matrix does not hold, of course, for \( L = 0 \) systems (or \( s \) states such as the hydrogen atom). The first consequence of the tensorial nature of \( g \) is that the magnetic moment of an unpaired electron in a real chemical system is not, in general, exactly antiparallel to the effective spin, and its magnitude is not simply that of a free electron but depends on the orientation of the system in the magnetic field. This can be expressed by Equation (34):

\[
\mu_s = -\mu_B gS
\]  

(34)

which formally clarifies how the (3 \( \times \) 3) \( g \) matrix acts on the (3 \( \times \) 1) \( S \) vector. In any arbitrary coordinate system fixed in the crystal the \( g \) tensor has the general form

\[
\begin{bmatrix}
 g'_{xx} & g'_{xy} & g'_{xz} \\
 g'_{yx} & g'_{yy} & g'_{yz} \\
 g'_{zx} & g'_{zy} & g'_{zz}
\end{bmatrix}
\]  

(35)

and is almost always symmetrical (\( g'_{xx} = g'_{yy} \)). In experimental terms (for a sample constituted by a single crystal having all the paramagnetic centers similarly orientated

Figure 11 (a) A radical cation of the family of pagodane with \( X = \text{CH}_2 \) or \((\text{CH}_2)_2\) and (b) its EPR spectrum, showing the complete spectrum above and a magnification of the central part below. (Reproduced from Prinzbach et al. with permission of VCH-Verlagsgesellschaft mbH.)
with respect to the crystal axes), the presence of a $g$ matrix is the cause of the dependence of the resonant field on the orientation of the crystal axes in the magnetic field. This is illustrated in Figure 12(a–d), where the simulated spectra of a paramagnetic center (with $I = \frac{3}{2}$) in a single crystal are reported for four different orientations of the paramagnetic center axis in the field. The anisotropy of $g$ is reflected in the different positions of the resonant fields for the various orientations and the anisotropy of $A$ in the different hyperfine separations between the four spectral lines. The example shown in Figure 12(a–d) is an ideal case in fact, because in real systems the orientation of the paramagnetic species axes is, in principle, unknown.

The structure of the $g$ tensor is therefore derived by running the EPR spectrum several times for various orientations of the crystal axes with respect to the magnetic field (Figure 13). The $(3 \times 3)$ $g$ matrix in Equation (35) is thus built up and then can be diagonalized by a mathematical operation that allows one to obtain the principal values of the tensor (Equation 36):

$$
\begin{pmatrix}
g_{xx} & 0 & 0 \\
0 & g_{yy} & 0 \\
0 & 0 & g_{zz}
\end{pmatrix}
$$

This operation is equivalent to a rotation of the Cartesian axes, after which the axes of the tensor (often, but not always, coinciding with molecular axes) and the laboratory axes coincide. In the first three cases in Figure 12(a–c) the direction of the external magnetic field coincides with the three principal axes of the paramagnetic system, two of which (Figure 12b and c) are equivalent and give rise to two coincident EPR spectra. The reported system is said to have an axial symmetry. The orientation in Figure 12(a) is called "parallel" and those in Figure 12(b) and (c) are called "perpendicular". The three values $g_{zz} = g_0$, $g_{xx} = g_{yy} = g_\perp$ derived from the resonant fields $B_z, B_x = B_y (g_0 = \hbar/\mu_B B_z$, Equation 8) and corresponding to the principal orientations (Figure 12a–c) are the diagonal elements of the matrix in Equation (36). In the more general case of rhombic symmetry, the three diagonal elements of the tensor have distinct values. The principal $g$ values of a given system can be evaluated theoretically, in terms of the deviation from $g_0$ caused by the spin–orbit interaction, using perturbation theory and considering the second and third terms of Equation (32) as perturbations of the spin-Hamiltonian. In this way it can be shown that a given element of the $g$ tensor can be expressed by Equation (37):

$$
g_{ij} = g_0 \delta_{ij} + 2\lambda \sum_{n=0} \frac{|0\rangle \langle n| L_i |n\rangle \langle L_j |0\rangle}{E_n - E_0}
$$

**Figure 12** Simulated four-line EPR spectra of an $S = \frac{1}{2}, I = \frac{3}{2}$ system in a single crystal for different orientations of the crystal in the magnetic field. In the scheme the directions of the radical axes and of the crystal axes are arbitrarily assumed to be the same.

where $\delta_{ij}$ is the Kronecker delta ($\delta = 0$ for $i \neq j$ and $\delta = 1$ for $i = j$), $L_i$ and $L_j$ are the components of the orbital angular momentum operator, $0$ represents the ground state and $n$ the different excited states and $E_0$ and $E_n$ are the energies of the ground state and the excited states, respectively. The sum of the diagonal elements of a tensor is called the trace and this quantity is invariant under any rotational transformation of the axis system. This means that for a sample in highly fluid solution, where it undergoes rapid and random tumbling, the position of the resonance is determined by the average of the diagonal elements of the $g$ tensor. In this case the observed $g$ value is therefore given by Equation (38):

$$g_{av} = \frac{g_{xx} + g_{yy} + g_{zz}}{3}$$  \hspace{1cm} (38)

The absolute determination of the $g$ values may, in principle, be carried out by independent and simultaneous measurements of $B$ and $v$, using a gauss meter and a frequency meter, respectively, according to Equation (30).

In practice, the $g$ value can be also determined by comparing the field values at resonance for the sample investigated and that of a reference sample. As one can write (Equation 39)

$$hv = g_{ref}\mu_B B_{ref} = g\mu_B B$$  \hspace{1cm} (39)

provided that $v$ is invariant during the whole experiment, $g$ is given by Equation (40):

$$g = g_{ref} \frac{B_{ref}}{B}$$  \hspace{1cm} (40)

The usual reference samples are diphenylpicrylhydrazyl (DPPH) ($g = 2.0036$), Varian Pitch ($g = 2.0028$) and $\mathrm{Cr}^{3+}$ in a $\mathrm{MgO}$ matrix ($g = 1.9797$). These reference samples give rise to narrow lines necessary for accurate determinations. The reference sample could be placed in one of the two compartments of a dual cavity or be stuck to the investigated sample quartz tube in the case of a single cavity.

Summarizing the concepts introduced in the present section, we have to recall that, measuring the position of the resonant field in an EPR spectrum, a $g$ factor ($g \neq g_e$) is determined (Equation 30) which depends on the electronic structure of the paramagnetic species and which is somehow equivalent to the chemical shift in NMR. The shift of $g$ from $g_e$ is due to partial contributions of the orbital angular momentum which take place through the spin–orbit coupling, and can be calculated as a perturbation of the spin-Hamiltonian (Equation 37). For spectra in the solid state the anisotropy of the magnetic interaction between $B$ and $S$ (the latter “modified” by the spin–orbit coupling) shows up in terms of different values of $g$ recorded for different orientations of the crystal in the magnetic field (Figures 12a–d and 13) and is formally expressed by a $g$ tensor (Equation 35) whose elements range between three limiting values ($g_{xx}$, $g_{yy}$, $g_{zz}$) which are the principal values of the same tensor in diagonal form (Equation 36). The cases of isotropic, axial and rhombic symmetries have been described for which all the axes of $g$ and the hyperfine tensor coincide. Cases with lower symmetry (not treated here for the sake of brevity) are the monoclinic and triclinic cases. In the monoclinic symmetry one axis of $g$ and one of $A$ are coincident, whereas in the triclinic symmetry there is complete noncoincidence of all axes. For spectra recorded in low-viscosity solutions a unique $g$ factor is observed, owing to the rapid molecular tumbling which is the average of the three principal values ($g_{av}$). In Table 2 the $g$ values of some $S = \frac{1}{2}$ paramagnetic species are reported.

### 3.4 Systems with $S > \frac{1}{2}$: the Fine Structure

The previous sections were devoted to the discussion of $S = \frac{1}{2}$ systems, i.e. of molecules or ions having one unpaired electron only. However, several paramagnetic systems have two, three or more unpaired electrons and consequently $S > \frac{1}{2}$. The relevant paramagnetic entities with $S > \frac{1}{2}$ are biradicals, molecules in excited triplet ($S = 1$) state, molecules in triplet, quadruplet ($S = \frac{3}{2}$) or quintuplet ($S = 2$) ground states, transition metal ions. The effect of the external magnetic field on the spin levels of an $S > \frac{1}{2}$ system is the splitting into $2S + 1$ Zeeman sublevels characterized by different $M_s$ values. The Zeeman splitting increases with increasing $B$ as in the $S = \frac{1}{2}$ case. The selection rule $\Delta M_s = \pm 1$ is still valid and produces $2S$ transitions. The position of the absorption

Energy levels for an $S = 1$, two electron spin system. In (a) there is a ZFS interaction and in (b) the ZFS interaction is zero.

lines, however, can vary markedly according to the extent of the so-called zero field splitting (ZFS) term. This term is a measure of the energy difference between the magnetic sublevels that occur in the absence of an external magnetic field and originates from the interaction between the magnetic moments of the various unpaired electrons. The interaction can be direct (for instance in the case of organic molecules in the triplet state) or can occur via spin–orbit coupling. The situation is illustrated in Figure 14(a) and (b) for the case of an $S = 1$ system. The separation between $M_s = \pm 1$ and $M_s = 0$ in the absence of a magnetic field is the ZFS. In terms of the spin-Hamiltonian the interaction between the two electron spins is expressed by Equation (41):

$$ H = D S D S $$

where $D$ is again a $(3 \times 3)$ traceless matrix analogous to the $A$ tensor (Equation 25) defined for the anisotropic hyperfine coupling. Also in the case of the electron–electron interaction (or fine interaction) the extent of the coupling varies as a function of the orientation of the paramagnetic center in the external field. Owing to some mixing between the various magnetic states, the $\Delta M_s = \pm 2$ transition (in principle forbidden) becomes partially allowed and appears, usually with weak intensity, at low field (Figure 14a).

In particular cases of high symmetry of the environment, the zero field separation for the various magnetic sublevels vanishes. The situation is reported in Figure 14(b) for $S = 1$. In this case the two allowed transitions occur at the same magnetic field value, resulting in a single resonance line. An experimental spectrum of a system in triplet state is reported in Figure 15.(4)

**4 SPECTRA OF POLYCRYSTALLINE MATERIALS (POWDER SPECTRA)**

In the previous section the role of anisotropy of both the electron–Zeeman and electron–nucleus hyperfine interactions was introduced and briefly discussed in the case of paramagnetic centers confined in a single crystal and therefore all having the same orientation. This was done because in the single crystal case (Figures 12a–d and 13) the main consequence of anisotropy (spectral features depending on sample orientation) clearly shows up. The very major fraction of the EPR spectra recorded in the solid state, however, does not come from single crystals but from polycrystalline materials or powders whose spectra are usually called “powder” spectra. As many chemical systems of interest are polycrystalline or cannot be easily prepared as single crystals, the practical interest in powder EPR spectra is very high. Powder spectra are recorded for various real chemical systems such as glasses, ceramics, catalysts, minerals, micro- and nanoporous materials and coordination compounds. Particularly important examples of powder spectra are obtained in the case of frozen solutions which are polycrystalline materials. The comparison of a solution...
spectrum with the corresponding spectrum of the frozen solution is usually very fruitful for the determination of the properties of the paramagnetic compound.

4.1 Line Shape of Simple Powder Spectra

A polycrystalline material is constituted by a large number of microcrystals randomly oriented in space so that all possible orientations of one crystal in the external field are equally probable. Since the sample is solid (the paramagnetic centers do not have the typical motion of a molecule in solution and in many cases can be considered immobile), the anisotropy of the various magnetic interactions influences the spectra and the values are not averaged as in the solution case. However, the experimental spectra, owing to the presence of all possible orientations of the microcrystals, are invariant to rotation and are basically constituted by an envelope of the single crystal spectra corresponding to all possible crystal orientations. Let us consider first the simple case of an $S = \frac{1}{2}$ paramagnetic center with no hyperfine splitting. The EPR spectrum is spread over the entire resonant field range ($\Delta B = B_{\text{min}} - B_{\text{max}}$) determined by the values of the principal $g$ components. The intensity of the powder spectrum, however, is not uniform over all the $\Delta B$ range as shown in Figure 16(a) and (b), in the case of an axial $g$ tensor ($g_{||} > g_{\perp}$) and in that of a rhombic tensor ($g_{xx} \neq g_{yy} \neq g_{zz}$), respectively. The nonuniformity of the intensity can be understood, in practical terms, taking into account (e.g. in the axial case) that, as $g_{xx} = g_{yy} = g_{\perp}$, the probability of having a microcrystal oriented in one of the two equivalent $x$ and $y$ directions is higher than the probability of an orientation along $z$. The relatively simple powder spectra lines reported in Figure 16(a) and (b) can become rather complex in the presence of hyperfine interactions. The whole shape of the hyperfine powder spectrum depends on various factors: the nuclear spin $I$ of the magnetic nucleus (or nuclei) interacting with the unpaired electron; the isotopic abundance of the magnetic nucleus; the symmetry of the hyperfine tensor (axial, rhombic, etc.) and the values of the various elements of the tensor itself.

Figures 17(a–c) and 18(a–c) illustrate some simulated spectral profiles due to species with axial $g$ tensors (Figure 17a–c) and rhombic $g$ tensors (Figure 18a–c) having nuclei with a given $I$ and different hyperfine constant values.

4.2 Powder Spectra of Some $S = \frac{1}{2}$ Transition Metal Ions

EPR spectroscopy has played a paramount role in the study of transition metal ions existing in inorganic molecular compounds, biologically important molecules such as metalloenzymes and solid materials. The interpretation of the spectra for paramagnetic transition ions having $S > \frac{1}{2}$ can be extremely complex and will not be discussed here. The reader is therefore referred to relevant books that treat this subject.\(^{6-9}\) We shall limit ourselves to the description of the features of some $S = \frac{1}{2}$ transition metal ions to illustrate with practical examples the role of the factors listed at the end of section 4.1 in determining the shape of the spectra. Let us consider the case of nd$^5$ ions such as Ti$^{3+}$, V$^{4+}$, Cr$^{3+}$ and Mo$^{5+}$, all having a single electron in the d orbitals. We shall examine first the structure of the $g$ tensor. These ions in coordination compounds or solid materials usually exhibit either octahedral or tetrahedral symmetry which splits the fivefold degenerate state of the free ion into two states, $t_{2g}$ and $e_g$, which are respectively triply and doubly degenerate (Figure 19a and b). The degeneracy of these states is further lifted by other effects, leading to structural distortions.

Two common cases which are relevant to EPR spectroscopy are illustrated in Figure 19(a) and (b), namely the tetragonal distortions by compression of
Figure 17 Calculated profiles of powder spectra of a species with axial $g$ tensor: (a) no hyperfine interaction; (b) and (c) two cases with hyperfine structure due to one $I = 1$ nucleus. The perpendicular component only shows appreciable hyperfine coupling.

Figure 18 Calculated profiles of powder spectra of a species with rhombic $g$ tensor: (a) no hyperfine interaction; (b) and (c) two cases with hyperfine structure due to one $I = 5/2$ nucleus. The only $x$ component shows appreciable coupling.

(a) tetrahedral and (b) octahedral structures. The latter, for example, is the typical structure of vanadyl (VO$^{2+}$) compounds. The $g$ values in the two cases are evaluated on the basis of the perturbation theory according to Equation (37).

For tetragonally distorted tetrahedral crystal fields (Figure 19a) one has

\[
\begin{align*}
\Delta_{\text{T d}} &= d_{x^2-y^2}, d_{z^2}, \quad \Delta_{\text{Oh}} = d_{y^2}, d_{x^2-z^2} \\
\end{align*}
\]

\[
\begin{align*}
\Delta_{\text{T d}} &= d_{x^2-y^2}, d_{z^2}, \quad \Delta_{\text{Oh}} = d_{y^2}, d_{x^2-z^2} \\
\end{align*}
\]

Simulated spectra for these two cases (in the absence of hyperfine interactions) are reported in Figure 20, showing...

\[ g_\perp = g_e - \frac{8A}{\Delta} \]

Figure 20 Schematic simulated EPR spectra of a 3d¹ ion with no \( I \neq 0 \) nuclei in distorted (A) tetrahedral and (B) octahedral crystal fields.

that EPR provides information not only on the nature of the paramagnetic ions but also on their coordination and on structural parameters such as the various crystal field energy splittings \( \Delta \). The schematic spectra shown in Figure 20 are amenable to the case of Ti³⁺ which, owing to the low abundance of the \( I = \frac{7}{2} \) ⁴⁹Ti nucleus, does not visually show any hyperfine structure or, at least, exhibits a very weak one. A real experimental spectrum of Ti³⁺ in tetragonal distorted octahedral coordination is shown in Figure 21, together with its computer simulation. Ti³⁺ ions are obtained by reducing Ti⁴⁺ ions embedded in the matrix of an ETS-10 zeolite (a molecular sieve of synthetic origin) where they are coordinated by six oxygen ions. The features of the spectrum, except for the line width, correspond to those in the schematic profile B in Figure 20. Traces of the hyperfine structure due to ⁴⁹Ti are visible at the left-hand side of the spectrum. Mo⁵⁺ and V⁴⁺ ions have the same d¹ electronic structure as Ti³⁺ and therefore, in a corresponding coordinative environment, also exhibit the same structure of the \( g \) tensor. The spectral profile under these conditions, however, is complicated by the presence of hyperfine structures due to magnetic nuclei. These are ⁹⁵Mo and ⁹⁷Mo \( I = \frac{5}{2} \) (overall abundance 25.3%) in the former case and ⁵¹V \( I = \frac{7}{2} \), abundance about 100% in the latter. The spectra (and corresponding simulations) of Mo⁵⁺ and V⁴⁺ ions both stabilized at the surface of TiO₂ in two different heterogeneous catalysts are shown in Figures 22 and 23, respectively. The stick diagrams in the figures evidence the hyperfine structure which is (partially) resolved for the perpendicular component only in the case of Mo⁵⁺ (the parallel structure is buried in the broad \( g_\parallel \) line). The high abundance of ⁵¹V determines the complex profile of the V⁴⁺ spectrum (Figure 23) where the two eight-line hyperfine structures \( (I = \frac{7}{2}, \text{number of lines } 2I + 1 = 8) \) are widely overlapped. Furthermore, for second-order effects not discussed here, the spacing between the hyperfine lines is not exactly the same, and grows from low to high magnetic field. Comparison of Figures 21, 22 and 23 illustrates the complexity that can be attained by a powder EPR spectrum and outlines the need for spectral simulations to determine exactly the spin-Hamiltonian parameters (\( g \) and \( A \) tensors).

4.3 A Pragmatic Approach to Powder Spectra Interpretation

In sections 4.1 and 4.2 the intrinsic complexity of the EPR powder spectra profile has been shown even in the case of model spectra (Figures 17a–c and 18a–c). The real, experimental spectra are usually complicated by additional effects such as the presence in the sample of various distinct species having different parameters, the presence of various nuclei with different nuclear spins in the same species and the broadening of lines due to spin–spin interaction or motional phenomena causing loss of resolution. For the above-mentioned reasons the evaluation of the spin-Hamiltonian parameters in the case of powder spectra is often performed by adopting additional techniques that may help in the assignments. The main additional tools which are employed are isotopic labeling, the multifrequency approach and the systematic use of computer simulation of experimental spectra. All
Figure 21 Experimental and simulated EPR spectra of Ti$^{3+}$ ions (3d$^1$) in the octahedrally distorted crystal field of a molecular sieve.

these techniques will be briefly discussed in the following sections.

4.3.1 Isotopic Labeling

The isotopic labeling technique is employed in EPR for at least two distinct reasons. In the first case, isotopes having nuclear spin $I = 0$ are substituted in the paramagnetic center by other isotopes with $I \neq 0$. In this case it has to be mentioned, for the sake of clarity, that the isotopic labeling is not used to help in the assignment of a complex spectrum, as indicated at the beginning of this section, but to obtain a hyperfine structure and the related information (nature of the atoms interacting with the unpaired electron, extent of this interaction) otherwise absent if $I = 0$. A typical case is that of oxygen radical species obtained using reactants enriched with $^{17}$O ($I = \frac{5}{2}$), since natural oxygen contains mainly $^{16}$O with $I = 0$. In the second case the isotopic labelling is indeed used to elucidate the structure of complex signals by comparing spectra of species having different isotopic composition. An example of this technique is reported in Figure 24 where (upper spectrum) the complex X-band signal of powdered MgO$_2$ obtained by reaction of magnesium oxide with H$_2$O$_2$ is reported. The signal is complex and is due to several oxygen-based paramagnetic species embedded in the solid matrix. However, two of the spectral lines (namely A and B, centered at $g = 2.0137$) were thought to be due to hyperfine interaction of an unpaired electron and a $^1$H nucleus both belonging to an OH radical. The combined use of isotopic labeling, the multifrequency approach and computer simulation, has been determinant in performing this assignment.

The substitution of $^1$H by $^2$H (using D$_2$O$_2$ instead of H$_2$O$_2$ in MgO$_2$ synthesis) leads to the lower spectrum in Figure 24 where the A–B pair (57 G separation) transforms into a triplet of about 9 G separation (partially buried in the intense central line). This is because $^1$H has $I = \frac{1}{2}$ and two lines $(2I + 1)$ are expected for the interaction of the unpaired electron with one proton whereas, in the case of deuterium, $I = 1$ and a three-line structure therefore arises. The hyperfine constant (i.e. the separation between the hyperfine lines) is in
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 23 Experimental and simulated EPR spectra of V$^{4+}$ (3d$^1$) ions at the surface of a V$_2$O$_5$/TiO$_2$ catalyst. The stick diagram evidences the hyperfine structure due to the 100% abundant $I = \frac{7}{2}$ $^{51}$V nucleus.

the case of deuterium about 6.5 times smaller than that recorded for $^1$H. This is due to the different values of the nuclear factor $g_n$ (Equation 13) for the two nuclei whose ratio $g_n(\text{H})/g_n(\text{D})$ is indeed 6.51. The use of deuterium instead of hydrogen has therefore allowed the assignment of two of the lines in the complex spectral envelope of Figure 24 to an H hyperfine structure due to one H nucleus.

4.3.2 Multifrequency Approach

The multifrequency approach is an excellent tool for understanding spectra of powder solids in which anisotropies of the tensor give rise to considerable complexity. The principle of this approach is based on the fact that the magnetic field separation $\Delta B$ between two lines due to anisotropy of the $g$ tensor varies linearly with the microwave frequency according to Equation (46):

$$\Delta B = \frac{h\nu}{\mu_B} \left( \frac{1}{g_1} - \frac{1}{g_2} \right)$$  \hspace{1cm} (46)

which is directly derived from Equation (29). The same does not apply to the separation of hyperfine lines arising from the interaction between the nuclear spin and the unpaired electron, which is unaffected by microwave frequency changes (see Equation 23). The use of a high-frequency mode, for instance, instead of a classical X-band mode, increases, for a given paramagnetic center, the magnetic field separation of the various $g$ components, but does not influence the hyperfine line separation. This effect is very useful in the case of X-band spectra with overlapping hyperfine structures whose features can be better resolved by running a high-frequency spectrum. The most commonly used bands (alternative to the classical X-band at about 9.5 GHz) are the low-frequency S band (see Table 1), the Q-band at about 35 GHz and the W band (94 GHz), which has been commercially available since the mid-1990s. The Q-band spectrum of the system described in the previous section (OH radical and other oxygen radicals in MgO$_2$) is reported in Figure 25 together with its computer simulation. The spectrum in Figure 25 confirms the existence of a doublet of hyperfine lines at $g = 2.0137$ separated by 57 G, but reveals another doublet ($g = 2.0038$, 25 G hyperfine separation) overlapped to the other spectral lines in the X-band spectrum of Figure 24, also belonging to the OH radical. The OH radical spectrum has a third broad and uncoupled feature at $g = 2.050$.

Figure 24 X-band ($\nu = 9.5$ GHz) powder spectra of various oxygen radicals trapped in a solid MgO$_2$ matrix obtained by contacting MgO with (A) hydrogen peroxide and (B) deuterium peroxide. The main lines due to the trapped hydroxyl (OH) or deuteroxyl (OD) radicals are evidenced by the stick diagram.
4.3.3 Simulation of Experimental Powder Spectra

The set of spin-Hamiltonian parameters obtained from an experimental EPR spectrum (not only for powder spectra but also for single-crystal and solution spectra) may be confirmed, to avoid ambiguity, by computer simulation of the spectrum on the basis of a given set of data, usually including the various tensors included in the spin-Hamiltonian \( g, A, D \), the line shape and the line width. Computer programs based on various approaches (from first-principle calculations to crude approximations) are available which calculate a spectral profile on the basis of input data. The exactness of the fit with the experiment can be checked by visual comparison of the two spectral patterns or via best-fitting computer programs based on standard mathematical approaches such as Monte Carlo or simplex methods. Computer simulation of the experimental spectra reported in this section [oxygen-based radicals in MgO\(_2\)]\(^{(19)}\) gave rise to the spectra reported in Figures 25 (Q-band spectrum) and 26(a) and (b) (X-band spectra with H and D hyperfine structure, respectively) The three different simulated profiles were obtained using exactly the same \( g \) tensor and using hyperfine values in the correct 6.5 : 1 ratio as would be expected on passing from H to D. The exactness of the fit for the three different experimental spectra definitely confirms the self-consistency of the set of spin-Hamiltonian parameters introduced in the simulation, which are reported in Table 3. The total number of species identified in the MgO\(_2\) matrix is three. Two are O\(^{−}\) and O\(_2^{−}\) radical ions and the third is the OH radical, the observation of which at room temperature is very uncommon owing to its high reactivity. The reported example should have shown that, in certain cases, a single experimental X-band spectrum is not sufficient to determine all the spin-Hamiltonian parameters of a given species, whereas a more complex approach based on complementary techniques allows, in some

4.4 Solid-state Versus Solution Spectra

The role of anisotropy of the magnetic tensors in causing complexity of the EPR spectra has been emphasized above. It is useful to summarize here the main practical consequences of anisotropy on the spectra in three limiting cases treated in this work, i.e. a solid single crystal, a polycrystalline solid and a low-viscosity solution. The complex cases of high-viscosity solutions or of liquid crystals are not considered here.

Single crystals: the anisotropy of $g$ shows up in terms of different resonant fields for different orientation of the crystal in the external magnetic field. (Figure 12a–d). The anisotropy of $A$ results in different hyperfine line separation, again according to the crystal orientation.

Polycrystalline solids. The anisotropy of $g$ and $A$ is observed in these spectra, which are (section 4.1) an envelope of all possible single-crystal spectra. The determination of all the principal values of the tensors is not straightforward and various methodological approaches (section 4.3) are adopted.

Solutions: molecular tumbling at a high rate has the effect of averaging the principal values of the tensors. In the case of $g$ a $g_{\text{av}}$ value is observed (Equation 38) whereas, in the case of the hyperfine tensor, the traceless anisotropic part is averaged to zero and only the Fermi contact term ($a_{\text{iso}}$) is detected. Figure 27(a–d) illustrate the above discussion, reporting the simulated spectra of a Cu(II) compound in terms of single-crystal spectrum (two orientations), powder spectrum and solution spectrum.

$\text{Cu}^{2+}$ is a $3d^9$ $(S = \frac{1}{2}, I = \frac{3}{2})$ ion and, in the cases of the very common elongated octahedral or square-pyramidal structures, an axial $g$ tensor is expected, with

$g_{zz} = g_{\parallel} = g_e + \frac{8\lambda}{\Delta_1}$ \hspace{1cm} (47)

$g_{xx} = g_{yy} = g_{\perp} = g_e + \frac{2\lambda}{\Delta_2}$ \hspace{1cm} (48)

where $g_e$ and $\lambda$ have the usual meanings and $\Delta_1$ and $\Delta_2$ are ligand field energy splittings between metal d orbitals. In such compounds $g_{\parallel} > g_{\perp}$ and, for the four-lines hyperfine structure $A_{\parallel} > A_{\perp}$.

Figure 27 Simulated profiles of the EPR spectra of a Cu$^{2+}$ compound: (a) powder spectrum; (b) and (c) single-crystal spectra (two limiting directions); (d) solution spectrum.
5 ADVANCED ELECTRON MAGNETIC RESONANCE TECHNIQUES

5.1 Electron Nuclear Double Resonance

ENDOR spectroscopy was applied for the first time in 1956 by Feher in solids. The ENDOR experiment is based on the partial saturation of one of the EPR hyperfine lines with an intense microwave field. A second irradiating field in the radiofrequency region induces nuclear spin transitions, thereby altering the populations of the energy levels, and this change is detected by observing changes in the polarization of the saturated EPR transition. Thus, in the ENDOR technique the NMR spectrum of a paramagnetic compound is measured indirectly via the electron spin. One of the principal advantages of the ENDOR technique over EPR is the higher resolution of the spectrum. The basic scheme of the ENDOR experiment is reported in Figure 28, where the EPR ($|\Delta M_S| = \pm 1$) and ENDOR ($|\Delta M_I| = \pm 1$) allowed transitions are shown. As a consequence of the different selection rules, the ENDOR spectrum shows a reduced number of lines and even in complex spin systems with many nuclei is usually still fairly simple.

The ENDOR spectrum of a paramagnetic compound in an external magnetic field can be described by means of the Hamiltonian in Equation (49):

$$H = \mu_B B g_S S - g_n \beta_n B I + I A S + I Q I$$  \hspace{1cm} (49)

which accounts for the electron and nuclear Zeeman interaction, the hyperfine interaction and the nuclear quadrupolar interaction. The last term causes only small shifts in the resonance frequencies. However, in the ENDOR spectrum, the quadrupolar coupling for nuclei with $I \geq 1$ is directly observed as splittings of the lines, giving useful information on the nuclear charge distribution. Furthermore, in the ENDOR experiment, equivalent nuclei, whatever the nucleus is, contribute to the spectrum with a pair of lines symmetrically disposed around $v_n$ ($v_n = g_n \beta_n B / h$), e.g. the Larmor frequency of the nucleus, and separated by the hyperfine splitting constant $A$ if $v_n > A/2$. When $v_n < A/2$ the resonance lines will be symmetrically disposed around $A/2$ and separated by $2v_n$. In general, the ENDOR frequencies are given by Equation (50):

$$v_{\text{ENDOR}} = v_n \pm \frac{A}{2}$$  \hspace{1cm} (50)

It is noteworthy that nuclei with different magnetic moments, e.g. different Larmor frequencies, will appear in different regions of the spectrum. Since the nuclear $g$ factors of most of the nuclei are known, the ENDOR spectrum allows the unambiguous identification of the nucleus under examination.

ENDOR spectroscopy thus offers a way around many of the common EPR problems such as poor resolution and inhomogeneously broadened spectra, the most relevant drawback being its lower sensitivity. Despite this disadvantage, ENDOR spectroscopy remains a powerful method for the analysis of unresolved EPR spectral lines, accurate measurement of hyperfine coupling constants, overlapping EPR signals due to the mixture of radicals or nonequivalent magnetic sites, measurement of the quadrupolar tensor.

5.2 Pulsed Techniques

So far our discussion has been restricted to CWEPR methods. We turn now to consider the field of time-domain EPR.13–15

In contrast to NMR spectroscopy, in which time-domain methodology has nowadays almost entirely superseded the conventional continuous wave (CW) methods, time-domain EPR has had a much shorter history, basically for technical reasons. The physics of the spins in both cases is essentially the same but the timescale characterizing the behavior of electron spins is much shorter than that for nuclear spins and this makes the technology needed for pulsed EPR experiments much more demanding. In recent years, however, pulsed EPR spectroscopy has undergone an extraordinary development and commercial instruments are now available.

In this section we shall limit ourselves to some introductory ideas about time-resolved EPR, introducing the basic features of pulsed EPR spectroscopy.

Let us consider a system made up by a number of electron spins $\mathcal{S} = \frac{1}{2}$ in an external magnetic field $B_0$. As stated in section 2.1, electron spins will be distributed at thermal equilibrium between the two Zeeman levels...
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 29 Evolution of the magnetization vector in a two-pulse electron spin-echo experiment. See text for explanation.

accordings to the Maxwell–Boltzmann law. This means that an excess of magnetic moments parallel to the applied field (β state, lower energy) will be present and a macroscopic magnetization $M_z$ in the direction of the applied static field will be established (Figure 29a). In order to understand the time-dependent EPR experiment we start by describing the behavior of the spin magnetization vector $\mathbf{M}$, precessing about the static magnetic field direction (Figure 29b). Upon the application of a short intense microwave pulse, the magnetization vector is rotated through $90^\circ$ in the rotating frame (i.e. a coordinate system rotating with the precessing electron spin magnetization vector about the static magnetic field direction) into a plane perpendicular to the field direction. $M_z$ is made up of the contributions of all the spins present in the system; since these spins are subjected to different “local fields” once the pulse is turned off, the magnetization vectors of the individual spins lose their coherence and precess apart (Figure 29c). The oscillating signal, which decays owing to transverse relaxation or inhomogeneous line broadening, is called free induction decay (FID). The Fourier transform (FT) of the oscillating signal in the frequency domain gives a spectrum consisting of peaks at the magnetization precessing frequency, which is identical with the CWEPR spectrum. Hence, in principle, the Fourier transform electron paramagnetic resonance (FTEPR) method allows the EPR spectrum to be recorded within a few microseconds. However, experimental limitations due to the short electron spin relaxation times make this technique, in practice, unsuitable for the majority of the spin systems. Nevertheless, in some restricted areas such as free radicals chemistry, FTEPR spectroscopy has reached a stage of development sufficient to make it an important tool especially for the investigation of short-lived paramagnetic species.

If a second pulse of twice the duration of the first is then applied to the system after a time interval $\tau$, the spin vectors are refocused back into phase at a time interval $\tau$ after the second pulse, producing the so-called Echo signal (Figure 29d). The evolution of the magnetization vector in the case of a two-pulse sequence $90^\circ–\tau–180^\circ–\tau$, which is the simplest one that can be used to generate a spin echo signal, can be followed in Figure 29(a–e). At time $t = 0$ the magnetization vector lies along the $z$-axis defined by the static magnetic field. The first $\pi/2$ pulse rotates the magnetization in the $xy$-plane after which the magnetization starts to decay for a time $\tau$ as the spin vectors spread out by virtue of their different precession frequencies. When a second pulse, $\pi$, is applied at a time $\tau$ after the first, all the spin vectors rotate at $180^\circ$ in the $xy$-plane. Then they continue to move in the same direction, at the same rate as before, until at a time $\pi$ after the second pulse they are all refocused and the magnetization vector is built up again, giving rise to the echo signal. Since the loss of coherence of the single spin vectors which constitute the magnetization vector $M_z$ is related to the spin–spin and spin–lattice relaxations, EPR spectroscopy provides a direct way of measuring relaxation times which can only be indirectly estimated with the usual CWEPR methods. Pulsed techniques also allow data on the kinetics of short-lived radicals to be obtained and in some cases the analysis of the spin echo spectrum also provides useful information about hyperfine coupling.

The way in which echoes reflect hyperfine interaction will now be briefly described. Until now we have limited our attention to the case of electron spin only. Under certain circumstances, however, a lot of information about hyperfine coupling can be achieved via the echo experiment. A nuclear spin in the vicinity of the unpaired electron will experience a magnetic field that results from the external field and the dipolar field from the unpaired electron. The nuclear spin will precess about this
field, producing a modulation of the dipolar field at the electron due to the nuclear spin. The main consequence of this phenomenon, known as electron spin echo envelope modulation (ESEEM), is that a plot of echo amplitude versus delay time often displays periodic modulation due to hyperfine interactions of the unpaired electron with nearby nuclear spins.

6 ANALYTICAL APPLICATIONS OF ELECTRON PARAMAGNETIC RESONANCE

It should be clear from the previous sections that EPR is basically an experimental research technique, extremely useful for structural investigations of various systems, rather than being a routine analytical technique. Nevertheless some applications of the technique having an analytical character have been proposed in the recent past and are briefly described in this section.

6.1 Spin Trapping

Spin trapping is an indirect technique for detection, identification and quantitative determination of free radicals in solution. The direct detection of highly reactive short-lived free radicals in fact is possible only for high concentrations of in situ-produced radicals generally obtained by irradiation or via a rapid-mixing flow system. The spin-trapping technique is based on the reaction of a free radical with the double bond of a diamagnetic compound to produce a less reactive radical. The diamagnetic compound is called the spin trap. The spin-trapping technique, very useful in general for studying short-lived reactive radicals, is essential for detecting radicals at very low concentration or with extremely short relaxation times (broad lines). Typical spin traps are nitroso compounds and nitrones. The well-known and widely employed 5,5-dimethylpyrroline N-oxide (DMPO) belongs to this latter class and reacts according to Scheme 1, which leads to the formation of a cyclic nitroxide. The nitroxide spin adducts derived from nitroxones usually exhibit EPR spectra characterized by hyperfine interaction with nitrogen and with the $\beta$-hydrogen. The magnitude of the hyperfine coupling is dependent on the nature of the radical species. Therefore, the identification of the trapped radical is not straightforward and is based on the careful measure of the hyperfine constants and on the comparison of their values with those of reference compounds. In Figure 30(a) and (b) the spectra of the adducts of hydroxyl radicals ($\text{OH}^*$) and $\text{CO}_2^-$ radicals with DMPO are shown with the relative stick diagrams illustrating the origin of the two different sets of lines. Double integration of the first-derivative signals and comparison with suitable references allows quantitative estimation of the amount of radicals present in a given system (spin counting).

6.2 Radiation Dosimetry

The accurate measurement of absorbed radiation dose is critical to the proper and effective use of ionizing radiation. A precise determination of absorbed dose is crucial in order to give accurate treatments in nuclear medicine, clinical radiology, food irradiation, the sterilization of medical devices, waste management and a wide variety of agricultural and industrial applications.

Ionization processes, along with excitations in atoms and molecules arising from the interaction between matter and ionizing radiation, are at the basis of the effects induced by radiation in biological tissues. A major task is to correlate the observed effects with the physical characteristics of the radiation field. This can be achieved by introducing a quantity known as absorbed dose ($D$) which represents the absorbed energy per unit of mass ($D = dE/dm$) and is measured in

![Figure 30](image-url)
gray, \((\text{Gy} = \text{Jkg}^{-1})\). The absorbed dose can be directly evaluated by measuring the energy transferred to the matter (calorimetry) or indirectly, by measuring radiation effects such as fission track, thermoluminescence (TL), phosphorescence and optical absorption. Among the possible products originated by ionizing radiation are free radicals whose concentration can be determined by means of EPR spectroscopy. If these radicals are sufficiently stable and a linear correlation between the EPR signal intensity and the absorbed dose exists, then the absorbed dose can be measured. The intensity of an EPR signal originated by radiation is proportional to the radiation dose rate, \(D\), and the irradiation time, \(t\). The dose–response curve is simply described by Equation (51):

\[
I(t) = kDt
\]

where \(k\) is a constant. The correlation between EPR signal and absorbed dose is obtained by means of a calibration curve. EPR dosimetry can be applied to a wide variety of materials and a few examples will now be given.

Alanine has been studied as a dosimetric system since 1962.\(^{21}\) Owing to the high thermal stability of the radicals generated by ionizing radiation, EPR/alanine dosimetry has been recognized as one of the most appropriate systems for monitoring the entire dose range from 10 to \(10^4\) Gy. The interaction between ionizing radiation and solid-state alanine gives rise to radical species, among which the stable radical \(\text{CH}_3\text{−CH−COOH}\), predominant at room temperature, exhibits a pronounced EPR spectral pattern. The signal intensity, obtained by double integration of the spectrum, is proportional to the concentration of unpaired spins (e.g. \(\text{CH}_3\text{−CH−COOH}\) radicals) and allows accurate and reliable absorbed dose measurement. EPR/alanine dosimetry has been studied in radiation processing plants, radiotherapy and an accelerator radiation environment. Another advantage of alanine is its chemical composition, which is close to that of tissue and makes this amino acid very suitable for neutron dosimetry.

Organic materials other than alanine can also be used as a tissue-equivalent dosimetric material. One example is represented by sugar. Sugar has been found to be sensitive to radiation down to 1 mGy. Sugar samples collected from houses have been used as an accident EPR dosimeter in the case of the Chernobyl reactor accident.\(^{22}\)

One of the best biological dosimeters, however, is tooth enamel. Teeth consist of three main tissues: dentine, enamel and cement. Enamel contains 95–98% hydroxyapatite \([\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]\) and a few percent of organic materials. Owing to their stability, radiation-induced \(\text{CO}_2^-\) radicals in hydroxyapatite have been extensively used for EPR dosimetry. EPR of tooth enamel has been applied to dosimetry of cancer patients under radiotherapy, to the cumulative X-ray dose used by dentists and to human dosimetry of radiation accidents. Other biological materials suitable for EPR dosimetry are shells, e.g. marine carbonates sensitive to radiation. Shell buttons have been used in atom-bomb radiation dosimetry.

Another field where EPR dosimetry is gaining more and more importance is the detection of irradiated foodstuffs. Irradiation is becoming an important method of food preservation and the first alternative process to the use of heat to kill microorganisms in food. Food irradiation can be used to reduce or eliminate food spoilage microorganisms, so extending the shelf life of food and improving its safety. Nevertheless, a precise determination of the absorbed dose is crucial in order to

![Figure 31](image-url)
know whether this is within the safe upper dose endorsed by the World Health Organization (WHO) which has been set at 10 kGy. EPR dosimetry is a simple (no sample pretreatment is required) and nondestructive method for the detection of radiation-induced unpaired electrons in irradiated food. EPR spectra of some irradiated foods are shown in Figure 31(a–d). CO$_2^-$ radicals in bones and shells have been used for the dosimetry of irradiated poultry, fish and frog bones. Irradiated meat, vegetables and spices have also been investigated by means of EPR dosimetry.

### 6.3 Electron Paramagnetic Resonance Dating

Another intriguing application of EPR dosimetry is in the field of archaeological and geological dating. The use of EPR as a dating technique is relatively recent. In recent years EPR dating has been applied to a number of different materials in various fields of earth science. Dating of carbonates, bones and tooth enamel in anthropological studies, and dating of burnt flints in archaeological applications have been carried out. EPR dating of geological fault movement, sun-bleached sediment and shock metamorphism has also been reported.

In EPR dating, the sample under investigation acts as a dosimeter, absorbing the doses from all radioactive sources in its immediate environment. Sources of radiation are cosmic rays and natural radioactive emitters such as the isotopes of the U- and Th-decay chains and $^{40}$K. The interaction between ionizing radiation and matter gives rise to a number of paramagnetic species which show characteristic EPR spectra. The intensity of the EPR signal is proportional to the concentration of the paramagnetic species and hence to the strength of the dose rate and the time of irradiation (age). An EPR age is thus derived from Equation (52): 

$$ \text{age} = \frac{TD}{D} $$  \hspace{1cm} (52)

where $TD$ is the total dose of natural radiation received by the sample since its formation or its last zeroing, and $D$ is the dose rate. It is worth pointing out that an EPR signal intensity does not indicate the radiation dose or the age unless the intensity is calibrated to the dose. The calibration can be set by the additive dose method, which consists in the exposure of the sample to increasing $\gamma$- or $\beta$-doses and in the extrapolation of the EPR signal intensity to zero (Figure 32). The dose rate ($D$) is derived from the chemical analysis of the radioactive elements of the sample and its immediate environment. In some cases the calibration of the EPR signal intensity can be obtained without radiation assessment. Several types of sample have annual growth lines, such as tree rings, which can be exploited to correlate the EPR signal intensities with the elapsed time in order to estimate the $TD$ directly. This method is known as EPR dendrochronology.

The signal intensity of radiation-induced defects is related to the EPR age and is considered to be zero for a sample of zero age. The following zeroing processes can be utilized for dating:

- **Crystallization:** this allows the dating of carbonate such as speleothems, mollusc shells, corals, tooth enamel, gypsum and halite.
- **Action of heat:** defects produced by natural radiation are annealed by heating. This zeroing process allows the dating of volcanic minerals or materials fired by ancient man.
- **Sunlight:** shining light on materials leads to optical bleaching of the defects. This mechanism allows, in principle, the dating of sediments.
- **Pressure:** plastic deformation resets the EPR signal in quartz and ionic oxides.

The dating range of a specific EPR signal is mainly dependent on its radiation sensitivity and its thermal stability. An upper limit of billions of years has been proposed, based on the correlation between geological age and the $E'$ center in quartz grains. The lower limit in EPR dating depends on the signal-to-noise ratio, the detection limit of the spectrometer and the presence of overlapping impurity signals. In certain cases the lower limit can be reduced to about 10 years ($TD = 10$ mGy).

A wide variety of materials and geological and archaeological events can, in principle, be dated by
EPR spectroscopy. The basic requirement is that the defects are stable for a sufficient length of time or a zeroing process, according to the events previously described, has occurred. Samples whose TDs have so far been determined by EPR spectroscopy include carbonates (stalacites, travertine, coral, shell, etc.), sulfates (anhydrite and gypsum), phosphates (hydroxyapatite, tooth, bone, etc.), silica and silicates (geological faults, volcanic rock, clay minerals) and organics (food, crops, leather, paper, alanine, mummies, blood).

EPR dating, owing to the large variation of materials and geological and archeological events to which this technique can be applied, has, in principle, one of the greatest potentials among dating methods. None the less, some problems have still not been conclusively solved. It is worth pointing out that an EPR result depends upon up to 15 independent factors and each can be influenced by various processes. EPR dating also lacks routine sample-preparation techniques, measurement conditions, signal definition, TD determination techniques and age-calculation programs.

High-performance Liquid Chromatography Nuclear Magnetic Resonance

Harry C. Dorn
Virginia Polytechnic Institute and State University, Blacksburg, USA

1 Introduction

The direct coupling of high-performance liquid chromatography (HPLC) to nuclear magnetic resonance (NMR) has evolved as a powerful new tool (HPLC/NMR) for the analysis of mixtures. The technique was originally reported in the late 1970s, but was generally limited by NMR detector sensitivity constraints and the availability of routine high magnetic field dispersion instruments (11.8–17.6 T, 500–750 MHz 1H-NMR). During the early 1980s, the HPLC/NMR technique continued to evolve and was applied to problems involving the analysis of mixtures that were typically not sample limited, such as petroleum fuels (see section 3.1). In the early 1990s, the major growth of HPLC/NMR as a viable analytical tool occurred after the commercial introduction by the NMR manufacturers Bruker and Varian. With the advent of commercial instruments, the number of laboratories worldwide with HPLC/NMR instrumentation increased by at least 10-fold during the 1990s to over 150. During this time, the availability of high-field NMR superconducting magnets (11.8–17.6 T, 500–750 MHz 1H-NMR) has helped alleviate sensitivity constraints and improved spectral dispersion. The HPLC/NMR technique has evolved as a powerful tool for applications in pharmaceutical and related biological industries (see section 3.3). With these developments, it is not difficult to predict that HPLC/NMR will continue to evolve as a powerful analytical tool.

One of the major advantages of NMR in comparison with other commonly employed chromatographic detectors is the high information content present in the NMR chemical shift dimension. The inherent advantage of monitoring the local electronic environment at each nonequivalent nuclear site (1H) in a molecule has distinct advantages in comparison with other chromatographic detectors, such as ultraviolet (UV), refractive index (RI), and MS. This is a particularly relevant point for those applications involving isomer identification (especially when coupled with MS, i.e. HPLC/NMR/MS). The non-invasive nature of the NMR detector also has distinct advantages for the characterization of air-sensitive and/or light-sensitive labile compounds.

1 INTRODUCTION

In 1978, Watanabe and Niki reported the first results for direct coupling of HPLC to 1H-NMR with stopped-flow detection. During the next two years, Bayer et al., Buddrus and Herzog, and Haw et al. extended the approach to continuous flow 1H-NMR detection (HPLC/ 1H-NMR). During the early 1980s, the HPLC/NMR technique continued to evolve and was applied to problems involving the analysis of mixtures that were typically not sample limited, such as petroleum fuels (see section 3.1). In the early 1990s, the major growth of HPLC/NMR as a viable analytical tool occurred after the commercial introduction by the NMR manufacturers Bruker and Varian. With the advent of commercial instruments, the number of laboratories worldwide with HPLC/NMR instrumentation increased by at least 10-fold during the 1990s to over 150. During this time, the availability of high-field NMR superconducting magnets (11.8–17.6 T, 500–750 MHz 1H-NMR) has helped alleviate sensitivity constraints and improved spectral dispersion. The HPLC/NMR technique has evolved as a powerful tool for applications in pharmaceutical and related biological industries (see section 3.3). With these developments, it is not difficult to predict that HPLC/NMR will continue to evolve as a powerful analytical tool.

One of the major advantages of NMR in comparison with other commonly employed chromatographic detectors is the high information content present in the NMR chemical shift dimension. The inherent advantage of monitoring the local electronic environment at each nonequivalent nuclear site (1H) in a molecule has distinct advantages in comparison with other chromatographic detectors, such as ultraviolet (UV), refractive index (RI), and MS. This is a particularly relevant point for those applications involving isomer identification (especially when coupled with MS, i.e. HPLC/NMR/MS). The non-invasive nature of the NMR detector also has distinct advantages for the characterization of air-sensitive and/or light-sensitive labile compounds.
2 THEORY AND OPERATING PRINCIPLES

Although standard high-resolution NMR normally utilizes samples spinning in cylindrical 5 mm tubes, a flow NMR detector represents different phenomenological and technical requirements. For example, the flow cell volume \( V_c \) is usually smaller than the 500–700 µL (5 mm tubes) typically employed in high-resolution static NMR studies. At present, commercial HPLC/\( ^{1} \)H-NMR instruments employ detector volumes \( V_c \) of the order of 50–150 µL (see Figure 1). In addition, considerable progress has been made (notably by Olson et al.) \(^{13}\) to extend this approach to nanoliter volumes.

Undoubtedly the major constraint in utilizing HPLC/NMR has been the sensitivity limitations of NMR as a detector. Although this factor has clearly limited development in the past, the advent of routine high-field NMR magnets (600–800 MHz, 14–19 T) has helped suppress this constraint. Furthermore, the recent development of cooled cryoprobes as NMR detectors promises further sensitivity gains by factors of 3–5. Figure 2 illustrates the present approximate detection limits for several detectors commonly employed in LC. It is apparent from Figure 2 that present commercial \( ^{1} \)H-NMR detectors have ultimate detection limits comparable with several common LC detectors, but fluorescence and MS still have a \( 10^2 \)–\( 10^4 \) sensitivity advantage. To provide a quantitative measure of the detection limits of HPLC/\( ^{1} \)H-NMR, several factors must be considered. Nevertheless, for molecules with molecular weights of 200–400 Da, continuous flow (1–4 s observation times) HPLC/\( ^{1} \)H-NMR detection limits of 5–2 µg are commonly achieved for 400–800 MHz \( ^{1} \)H-NMR detectors. For the case of stopped-flow \( ^{1} \)H-NMR measurements (several hours acquisition times) at these field strengths, a reasonable signal to noise ratio (S/N) can be achieved for samples of only 200–50 ng.

A second problem originally anticipated for the LC/\( ^{1} \)H-NMR technique was the limited choice of compatible chromatographic solvents (e.g. without hydrogen). This problem was originally alleviated by the use of extensive deuterated, chlorinated, and/or fluorinated solvents for normal-phase chromatography (e.g. freon 113, \( \text{D}_2 \text{O}, \text{or DCCl}_3 \)). In another approach, SFC coupled with \( ^{1} \)H-NMR has the advantage that certain common supercritical solvents (e.g. \( \text{CO}_2 \)) do not contain hydrogen. However, most state-of-the-art chromatographic separations utilize reversed-phase conditions and correspondingly large residual \( ^{1} \)H-NMR background signals are normally present in the reverse-phase deuterated solvents (\( \text{D}_2 \text{O}, \text{D}_3 \text{CCN}, \text{or CD}_3 \text{OD} \)) usually employed. In these cases, a number of solvent-suppression sequences have been successfully developed to eliminate one or more remaining spectral solvent lines. Originally, Laude et al. utilized a 1–1 hard pulse sequence for solvent suppression (97:3, \( \text{D}_2 \text{O}–\text{acetonitrile} \)) in a reversed-phase LC/\( ^{1} \)H-NMR separation of the nucleosides uridine, cytidine, and adenosine. \(^{17}\) Albert et al. have employed a binomial 1:3:3:1 sequence for solvent suppression of a 50:50 water–acetonitrile solvent system in a reversed-phase separation of several aromatic compounds (70 µg each). \(^{18}\) More recently, very effective solvent suppression of one or more spectral lines has been reported by Smallcombe et al. utilizing a water elimination \( T_1 \) (spin–lattice relaxation time) (WET) sequence. \(^{19}\) The very effective elimination of solvent peaks (as well as \( ^{13} \)C satellite lines is illustrated in Figure 3).

One phenomenological consideration of continuous flow HPLC/\( ^{1} \)H-NMR and flow NMR is the essential requirement that the flowing bolus must reside in the
Figure 3 A comparison of WET and conventional presaturation solvent suppression on a sample of 10 mM arginine in 50:50 CH$_3$CN (0.1% trifluoroacetic acid (TFA))–D$_2$O flowing at 1.0 mL.min$^{-1}$. Curve (a) used both transmitter and decoupler presaturation, each producing 40 Hz field strength 1.1 s square pulses, for the CH$_3$CN and monodeuterated water (HOD) resonances at 1.95 and 4.4 ppm, respectively. The residual center line of acetonitrile is plotted off scale. Curve (b) used WET without $^{13}$C decoupling, whereas curve (c) used WET with $^{13}$C decoupling. Curves (b and c) used 22.4 ms SEDUCE band-selective decoupling scheme pulses, the spin–lattice relaxation time ($T_1$) and $B_1$-insensitive (where $B_1$ is radiofrequency field) version of WET, a 10 ms $dz$ delay following the final gradient pulse (G4), and a composite read pulse. Each spectrum is the result of four scans, and was processed using 1 Hz line broadening (no solvent-deconvolution software was used). The acquisition times for (b) and (c) were 2.0 s (no zero filling), whereas the presaturation spectrum (a) required a 1.0 s acquisition time and zero filling to allow the repetition rate for all three spectra to be kept constant (at 2.1 s). (Reprinted with permission, J. Magn. Reson.)

magnetic field ($B_o$) for a time ($t$) that is long relative to the $^1$H-NMR $T_1$s ($\geq 3 – 4 T_1$s). This requirement ensures that the Boltzmann magnetization has sufficient time for equilibration in the magnetic field. For small molecules (100–300 Da) in solution the $^1$H $T_1$s are usually of the order of several seconds, but are considerably shorter ($<1 s$) for larger molecules. Thus, this requirement is usually satisfied at low flow rates and/or the use of pre-equilibration volume in the magnetic field. One ideal solution that has not been commonly implemented is the placement of the LC column directly in the magnetic field. A second consequence of flow is the effective residence time of the bolus in the detector cell, $t_c$. The average residence time of the bolus in the detector cell, $V_c$ can be expressed (Equation 1) as

$$t_c = \frac{V_c}{\bar{v}}$$

where the mean velocity $\bar{v}$ must be used. The mean velocity is defined because for other flow patterns (e.g. laminar) the velocity is a function of the distance from the detector cell walls. If one treats flow as a relaxation process, the lifetime broadening can be expressed as in
Equations (2) and (3):
\[
\begin{align*}
\frac{1}{T_1} \text{flow} & = \left( \frac{1}{T_1} \text{static} + \frac{1}{T_c} \right) \\
\frac{1}{T_2} \text{flow} & = \left( \frac{1}{T_2} \text{static} + \frac{1}{T_c} \right)
\end{align*}
\]

It is apparent from Equation (3) that the observed flow NMR line width \( \Delta v_{1/2} = (\pi T_2)^{-1} \) can exhibit a significant increase at high flow rates because of the limited residence time, \( t_c \). In contrast, static samples only exhibit contributions from spin–spin relaxation processes \( (T_2) \) and the magnetic field inhomogeneity. For example, Fyfe et al.\( \text{[21]} \) reported \( ^1\text{H-NMR} \) line width data for flowing ethylbenzene using a 5 mm outside diameter flow tube. A linear plot (Equation 3) was obtained as a function of flow rate with line widths ranging from 2.2 Hz (static) to 8 Hz (flow, 120 mL min\(^{-1}\)). The bolus lifetime problem becomes more acute with the progression to nanoliter-scale volumes.\( \text{[13]} \). For example, at a flow rate of 10 mL min\(^{-1}\) and a cell volume \( v_c \) of about 80 \( \mu \text{L} \), an average residence time \( t_c \) of about 0.5 s is readily calculated, which corresponds to an observed line width of several hertz. However, if a cell volume of only 800 nL is employed at the same flow rate, this corresponds to an NMR line width of several hundred hertz.

Finally, it is important to emphasize that the major focus of flow HPLC/NMR has been mainly limited to the \(^1\text{H} \) nuclide. The described sensitivity limitations of the NMR detector have generally led to only HPLC/NMR studies of NMR high-sensitivity nuclides (e.g. \(^1\text{H} \) and \(^19\text{F} \)). However, the extension to other less favorable nuclides such as \(^13\text{C} \) (section 4) is possible in future studies by indirect detection methods (via \(^1\text{H} \)) and/or stopped-flow approaches. It is also important to note that HPLC/NMR is one application for flow NMR and that several other flow experiments have been reported, such as recycled flow.\( \text{[12]} \)

3 APPLICATIONS OF HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY NUCLEAR MAGNETIC RESONANCE

3.1 Fuels

One of the first applications of HPLC/\(^1\text{H-NMR} \) was the analysis of fuel samples from petroleum, shale, and coal samples.\( \text{[22–26]} \) As these studies were not hampered by the availability of the sample, larger-scale chromatographic columns were commonly employed. These early examples illustrate the power of the HPLC/NMR approach and the critical importance of the chemical shift dimension.

**Figure 4** 200 MHz \( ^1\text{H-NMR} \) profile of the monocyclic region of a model mixture consisting of \( n \)-butylbenzene, xylene, and tetralin. A Whatman M9 10.50 PAC column was used with the solvent system freon \( 113–\text{CDCl}_3, 97.5:2.5 \). Hexamethyldisiloxane (0.05\%) was used as the reference. Each file represents 0.5 mL elution volume, 30 s per file. (Reprinted with permission from J.F. Haw, T. Glass, H.C. Dorn, \textit{JEOL News}, 18A, 6–9 (1982).)

For example, Figure 4 illustrates five progressive snapshots in the LC/\(^1\text{H-NMR} \) profile of the monocyclic aromatic region of a model fuel mixture. The progression from early-eluting compounds (\( n \)-butylbenzene, spectral file 18) to later-eluting compounds (\( m \)-xylene and tetralin) demonstrates resolution in the chromatographic sense. In spectral file 22 (Figure 4), two compounds (\( m \)-xylene and tetralin) that are not fully resolved chromatographically are easily identified along the chemical shift axis.

A practical example of LC/\(^1\text{H-NMR} \) utilizing a 200 MHz \(^1\text{H-NMR} \) detector is presented in Figure 5(a). A sample consisting of 100 \( \mu \text{L} \) of a jet fuel was injected and the data acquisition required 20 min. The HPLC/\(^1\text{H-NMR} \) profile is clearly more informative than LC or static \(^1\text{H-NMR} \) alone, providing a fingerprint for a fuel. The progression from linear alkanes to branched and cyclic hydrocarbons is readily apparent in files 2 to 7 (Figure 5a) for the aliphatic fraction of this fuel. In a similar fashion the monocyclic aromatic region clearly indicates a progression from short chain (3–4 alkyl carbons) monosubstituted aromatics in files 13 and 14 (Figure 5b) to di-, tri-, and tetra-methyl substituted aromatics in files 18–22 (Figure 5c). Methods for the determination of quantitative data from the HPLC/\(^1\text{H-NMR} \) profile of fuels using an internal standard have been reported.\( \text{[27]} \) Finally, properties such as density, freezing point, or aromaticity can be predicted from the HPLC/\(^1\text{H-NMR} \) profile.\( \text{[28]} \)

3.2 Polymers

One of the first series of detailed reports for analyzing soluble polymer mixtures was reported by Hatada and colleagues. During the 1990s, this group has utilized several chromatographic approaches,
including gel permeation chromatography (GPC) directly coupled to $^1$H-NMR (GPC/$^1$H-NMR) to analyze different soluble homopolymers, copolymers, and oligomers.\textsuperscript{29–33} In one study, chloral oligomers were separated in both the chromatographic and $^1$H chemical shift domain into dimer, trimer, tetramer, pentamer, hexamer, and heptamer fractions in the GPC/$^1$H-NMR profile.\textsuperscript{29} In a GPC/$^1$H-NMR study of isotactic poly(methylmethacrylates) (PMMAs) containing a single $t$-butyl end group, the molecular weights were directly determined from integration of the $t$-butyl and methoxy $^1$H-NMR signals.\textsuperscript{32} The on-line GPC/$^1$H-NMR profile for isotactic PMMA is shown in Figure 6, and the corresponding $^1$H-NMR-detected GPC curves are shown in Figure 7. In this latter figure, the RI curves are similar to the NMR data, but displaced in time because of differences in the void volumes of the two detectors. A linear plot of log ($M_n$) versus elution time was obtained from the $^1$H-NMR data profile.

More recently, Hatada and colleagues\textsuperscript{33} have reported a further study of the direct determination of molecular weight distribution of isotactic PMMAs ($M_n = 3.27 \times 10^3$–$4.44 \times 10^4$) utilizing site-exclusion chromatography (SEC)/$^1$H-NMR at the higher frequency of 750 MHz. In this study, the relative $^1$H-NMR intensity of the
end-groups was used as the internal standard (integrated relative to the repeating units) without recourse to the use of an internal standard. Also, the conditions were carefully optimized for quantitative measurements including the flow rate, pre-equilibration in the magnetic field, and other NMR operating parameters. The molecular weight distribution determined in this fashion was found to be accurate based on uniform isotactic PMMAs consisting of exactly 23, 40 and 80 repeating units. The results of this SEC$^1$H-NMR study were compared with the usual SEC/RI approach. The greater accuracy of the SEC$^1$H-NMR data that does not require a calibration curve was observed in this study, as were the advantages in S/N available at the higher operating frequency (750 MHz$^1$H-NMR).

Pasch et al.$^{35}$ have utilized HPLC$^1$H-NMR to analyze the tacticity of oligostyrenes. In this study, four separate isomers (1–4) in Scheme 1 of the trimer were

Scheme 1

Figure 8 Chromatograms and $^1$H methyl group regions of fractions 1 and 2 of the chromatographic separation of the trimer. (Reprinted with permission, Polymer.$^{34}$)
identified in two different chromatographic fractions, as outlined in Figure 8. The trimer fractions 1 and 2 each consist of two isomers with a small amount of fraction 1 eluting into fraction 2. The 500 MHz $^1$H-NMR spectral methyl region for these fractions clearly identifies eight different methyl groups (four triplets and four doublets). However, one set of triplets overlaps (at about 0.784 ppm) in both fractions. A highlight of this study was the use of pure acetonitrile with no deuterium lock.

### 3.3 Biological and Pharmaceuticals

With the advent of commercial high magnetic field equipment during the early 1990s by Bruker and Varian, the utility of HPLC/NMR has rapidly evolved for many pharmaceutical applications. For example, a series of papers illuminate the utility of HPLC/1H-NMR for the investigation of numerous urinary and bile metabolites. $^{(35-42)}$

In one pioneering study, the advantages of monitoring both the $^1$H and $^{19}$F chemical shift dimension of the HPLC/NMR profile for the human urinary metabolites of fluorine containing the drug, flurbiprofen (5) was nicely demonstrated (Scheme 2). $^{(40)}$

![Scheme 2](image)

The lack of any significant endogenous fluorine-containing compounds yielded a HPLC/$^{19}$F-NMR profile of only four major fluorine-containing metabolites (5–8) in Scheme 2. The four fluorine-containing metabolites were then further characterized using the HPLC/$^{19}$F-NMR approach.

In another study, $^{(41)}$ phase II metabolites of the nonsteroidal anti-inflammatory drug tolfenamic acid (9) were clearly separated in the higher field chemical shift dimension (800 MHz $^1$H-NMR) profile (Figure 9). This represents one of the first examples of direct identification of intact glucuronic acid conjugates of tolfenamic acid without $\beta$-glucuronidase treatment of the biological sample.

A 400 MHz and 600 MHz HPLC/$^1$H-NMR study of the isomers of 6,11-dihydro-11-oxodibenz[b,e]oxepin-2-acetic acid glucuronide (a nonsteroidal anti-inflammatory drug) has also been reported by this group. $^{(42)}$ This study illustrates the power of the $^1$H-NMR chemical shift dimension to monitor subtle structural changes (represented by $\alpha$ and $\beta$ anomers) which are involved in the acyl migration of isomers. Although the 2-, 3-, and 4-aryl transacylation products recovered from urine were chromatographically resolved, the $\alpha$ and $\beta$ anomers were not completely resolved.

Figure 10 is the 600 MHz $^1$H-NMR spectrum for the peak eluting at 11.68 min, and corresponds to the 3-O-acylg glucuronide anomers (12) and (13), Scheme 3. In this case, the $\alpha$ and $\beta$ anomers were present in nearly equal amounts, although the doublet resonance $H5\alpha$ signal ($\delta$ 4.30 ppm) is slightly suppressed relative to the $\beta$ anomer $H5\beta$ signal at $\delta$ = 3.97 ppm. The latter suppression is due to solvent irradiation of the HOD signal centered at $\delta$ = 4.35 ppm. This paper nicely illustrates the practical utility of HPLC/$^1$H-NMR in the characterization of drug glucuronides in whole biofluids. This study also demonstrates that a 400 MHz $^1$H-NMR detector was adequate for most glucuronides in this study, but the 600 MHz $^1$H-NMR detector provided better sensitivity and spectral dispersion for one pair of isomeric glucuronides.

In a study by Ehlhardt et al. $^{(43)}$ the metabolites of the multidrug resistance modulator CY335979 were identified in a more complex matrix, namely bile. The rat bile metabolic pathway is outlined below.

The HPLC/MS profile clearly distinguished (18) and (19) ($m/z = 720$; Scheme 4) from (20) ($m/z = 736$) because of a parent peak 16 mass units greater in value. However, the HPLC/$^3$H-NMR (500 MHz) profile was required to distinguish metabolites (18) and (19). As indicated in Figure 11, stopped-flow spectra HPLC/NMR spectra for peaks at 24.6 min and 24.8 min, corresponds to elution times for metabolite (18) and a mixture of (18) and (19), respectively. This work clearly illustrates the utility of the HPLC/NMR technique to analyze metabolites in both liver microsome and bile matrices.

Finally, the rapid identification of naphthylisoquinoline alkaloids in crude plant extracts using HPLC/NMR and rotating frame Overhauser enhanced spectroscopy (ROESY) was recently reported by Bringmann et al. $^{(44)}$
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 9 800 MHz one-dimensional $^1$H-NMR spectra obtained from an HPLC/NMR experiment on the 60% methanol solid-phase extraction (SPE) fraction of a urine sample containing metabolites of tolfenamic acid (Structure 9). The aromatic spectral region (δ 6.3–8.5) is shown for clarity. All the metabolites seen were present in the form of glucuronic acid conjugates, identified on the basis of the resonance of the β-1′ proton at δ 5.8 (not shown in the figure). Additionally, the metabolic state of the CH$_3$ side chain was identified on the basis of the presence of a singlet at δ 2.3. H3–H6 and H3′–H6′ are the protons on the aromatic rings of tolfenamic acid and its metabolites. Spectrum A corresponds to metabolite IXa (shown), B corresponds to metabolites 9a and 9b (shown), C corresponds to metabolite 9c (shown), and D corresponds to metabolite 9d (shown). (Reprinted with permission, Analytical Chemistry.$^{(41)}$)

4 MISCELLANEOUS APPLICATIONS

One important extension of the HPLC/NMR technique from the present NMR detection volumes of 50–150 µL is the progression to nanoliter volumes (i.e. 40–200 nL). The development of nanoliter level flow cells and corresponding NMR microcoils has been hampered in the past by the loss in spectral resolution usually observed in preparing these devices. This is usually the result of differences in the magnetic susceptibility of the sample, glass support, and micro-cell. However, Olson et al.$^{(46)}$ have made considerable progress in suppressing the problems associated with magnetic susceptibility variations. In one of the first applications in a study by Albert and colleagues, capillary HPLC/$^1$H-NMR was used to determine the structure of retinyl acetate dimers$^{(45)}$ at nanoliter detection volumes (ca. 200 nL). Another possible application of nanoliter-volume NMR detectors is for separations based on CZE which allows rapid and efficient separation of charged analytes and biomolecules in small volumes. A diagram of a CE/NMR experimental layout is shown in Figure 12. Recently, Pusecker et al.$^{(46)}$ extended the capillary electrophoresis (CE) approach to CEC which is carried out in packed capillary columns. The separation of some hop bitter acids (humolones and isohumlones) was reported by this group using stopped-flow CZE/NMR.

Another variant is SFC and supercritical fluid extractions (SFE) with $^1$H-NMR detection (SFC/$^1$H-NMR). This technique was originally reported in 1988 by
Allen et al. for the analysis of fuel samples. More recently, others have reported results for extraction of caffeine from roasted coffee (SFC/1H-NMR) and the extraction of alkyl and aryl phthalates (Figure 13) utilizing SFE/1H-NMR. One major advantage in both (SFC and SFE) is the avoidance of background signals with the most common supercritical fluid CO2.

Except for a few studies utilizing HPLC/19F-NMR, there have been relatively few reports employing other NMR active nuclides (such as 31P, 15N, and 13C) for HPLC monitoring applications. Clearly, a limitation in the past has been the poor sensitivity of other important nuclides (13C).

However, in the direct coupling of LC with 13C, DNP detection (LC/13C-DNP) has been employed to alleviate the sensitivity constraints of LC/13C-NMR. Work by Stevenson and Dorn has described directly coupled LC with continuous flow solid–liquid intermolecular transfer (SLIT) 13C-DNP detection using a silica phase immobilized nitroxide (SPIN) sample (LC/13C-DNP). Shown in Figure 14 is the LC/13C-DNP profile of a single injected component of chloroform with carbon tetrachloride as the chromatographic solvent. The LC/13C-DNP profile for the separation of chlorinated hydrocarbons is illustrated in Figure 15. Although this is a contrived example, it is noteworthy that in the corresponding flow 13C-NMR (no microwave irradiation) experiment no signals were detected. With the improved SPIN samples used in this study, a 13C-DNP enhancement of approximately 100 has been obtained in comparison with static thermal 13C-NMR Boltzmann magnetization at 4.7 T. Clearly, improvements in higher field superconducting magnet design, instrumentation, and other polarization transfer experiments will provide continued evolution of improvements in NMR signal enhancement.
5 PERSPECTIVE AND FUTURE DEVELOPMENTS

It is reasonable to assume that the HPLC/NMR technique will continue to evolve as one of the dominant tools in high-resolution NMR. The commercial expansion, from a nonexistent commercial product in the early 1990s to a market today with multimillion dollar sales, further support this development. The commercial availability of high-resolution and high-field superconducting magnets suggests continued advances in the HPLC/NMR technique. Additional related techniques include direct injection of samples, nanoliter scale volumes, and improved cryoprobe NMR detectors, providing complimentary supporting approaches for the flow and HPLC/NMR techniques. One of the
ultimate advantages of this technology is to reduce the labor-intensive preparation of individual sample tubes (and corresponding reference and lock material) for each separate sample. These conventional approaches also have the inherent problem of introducing new impurities. The HPLC/NMR technique is also readily amenable to monitoring photosensitive products or metabolites in a noninvasive fashion and can be readily coupled to other detectors (e.g. MS). As illustrated by the examples in this review, samples consisting of relatively complex matrices are readily analyzed by HPLC/NMR.

From the chromatographic perspective, the availability of commercial chiral chromatographic phases for separation of enantiomers suggests a future marriage of chiral chromatography with NMR detection as a new tool for pharmaceutical development of next-generation single-enantiomer drugs. The present limitation of HPLC/NMR to only the most sensitive NMR nuclides ($^1$H and $^{19}$F) will undoubtedly expand to other nuclides with reasonable sensitivity (e.g. HPLC/$^{31}$P-NMR) in the near future. Even nuclides with relatively poor sensitivity are potentially amenable with stopped-flow and inverse detection (via $^1$H) techniques.

Nuclear magnetic resonance (NMR) is associated with transitions, induced by radiofrequency (RF) irradiation, between energy levels of nuclei with nonzero spin quantum numbers in a magnetic field. Traditional “one-dimensional” (1-D) NMR spectra are presented as a plot of signal intensity versus applied frequency and provide information about the chemical environment of magnetically active nuclei. This is used to deduce information about the chemical structure and dynamics of molecules containing the magnetically active nuclei (most often protons). The frequencies of individual nuclei are referred to as their chemical shifts. Multidimensional NMR encompasses a range of related techniques, based on the application of a variety of precisely timed RF pulses to the sample, which extends traditional 1-D NMR into two-, three-, or four-frequency dimensions. These additional frequency dimensions may be the same as the first frequency dimension, referred to as homonuclear multidimensional NMR, or different, referred to as heteronuclear NMR. In multidimensional NMR of biomolecules, the most common frequencies correspond to $^1$H in the directly detected dimension and one or more of $^1$H, $^{13}$C, or $^{15}$N in the additional dimensions. Peaks in such spectra are defined by their intensity and frequency coordinates in two, three, or four dimensions obtained by extrapolation back to the respective frequency axes, which are in turn determined by the nature of the applied RF pulse sequences. The intensity and chemical shifts of such peaks provide information about the chemical environment, molecular connectivity, or spatial proximity of the participating nuclei. Multidimensional NMR has major advantages over 1-D NMR: reduction of peak overlap and provision of information on connectivity (either through bonds or through space). Multidimensional NMR spectroscopy of biomolecules is usually done for samples in solution at millimolar concentration. Where experiments require the use of $^{13}$C or $^{15}$N frequencies, it is usually necessary to isotopically enrich the macromolecule with these nuclei to >90%. This is readily achieved with modern molecular biology techniques and does not present a major limitation. The biggest limitation relates to molecular size, with studies generally limited to macromolecules of less than approximately 35 kDa.

1 INTRODUCTION
1.1 Physical Basis of Nuclear Magnetic Resonance Spectroscopy

NMR occurs when nuclei with nonzero spin quantum numbers (e.g. $^1$H, $^{13}$C, $^{15}$N) are placed in a powerful magnetic field and subjected to RF irradiation. The derived signals provide valuable information about the
structure and dynamics of molecules containing the NMR-active nuclei, making NMR spectroscopy one of the most powerful techniques for examining molecules in solution. As the basic theory of NMR spectroscopy has been covered elsewhere in this publication (see Nuclear Magnetic Resonance and Electron Spin Resonance Spectroscopy: Introduction), the theoretical details are not repeated here, where the focus is on aspects unique to multidimensional NMR of biomolecules. It is sufficient to provide a brief reminder that the essential features of NMR spectroscopy are a powerful magnetic field, which results in the alignment of magnetically active nuclei into a discrete number of orientations (dependent upon the spin quantum number), and an RF field that is sufficient to disturb the alignment of the nuclei from their equilibrium positions. The signals detected during recovery (relaxation) of the nuclear magnetization back to its equilibrium value are manifest as oscillating voltages in an RF receiver coil and are subsequently amplified and digitized. The data are usually presented as a spectrum (a plot of intensity versus one or more frequency dimensions). In addition to the information provided in earlier articles of this publication, the detailed principles of 1-D and two-dimensional (2-D) NMR are covered in the monograph by Ernst et al.,\(^1\) and the technical aspects of NMR relevant in biomolecular studies are addressed extensively by Wider.\(^2\) Theoretical\(^3\) and practical\(^4\) aspects of macromolecular NMR have also been addressed in recent monographs. This article focuses on NMR spectroscopy of proteins. The applications of NMR to studies of other biomolecules have been addressed elsewhere.\(^5,6\)

The general equation that governs the NMR phenomenon is Equation (1):

\[
f = \gamma B_0
\]

where \(f\) is the observed resonance frequency, \(\gamma\) is the gyromagnetic ratio of the nucleus concerned, and \(B_0\) is the applied magnetic field. The single most important factor that makes the NMR phenomenon useful in chemical and biological applications is that this basic frequency is moderated by the local electronic environment of the nucleus. Thus, the frequency of an individual nuclear spin in a molecule is given more correctly by Equation (2):

\[
f = \gamma (1 - \sigma) B_0
\]

where \(\sigma\) is a shielding factor (of the order of a few parts per million) that reflects the local electronic environment of the individual nucleus. This shielding factor is the origin of the so-called chemical shift that discriminates between chemically inequivalent nuclei of a given type (e.g. protons). The separation of NMR signals via chemical shifts allows site-specific information to be obtained even in complex biomolecules.

### 1.2 Instrumentation

As protons are the most sensitive and most commonly detected nuclei, an NMR instrument is often specified in terms of its nominal proton frequency. In general, the sensitivity of NMR instruments increases with increasing frequency, and because of the stringent sensitivity requirements for biological samples, 500 MHz system (corresponding to a magnetic field of 11.7 T) tends to be the entry level of spectrometer for biological applications. The spectrometers currently used for biomolecular studies typically include 500-, 600-, 750-, and 800-MHz systems, with 900-MHz system on the immediate horizon. These systems utilize superconducting magnets, which are based on a solenoid of a suitable alloy (e.g. niobium/titanium or niobium/tin) immersed in a dewar of liquid helium. The extremely low temperature of the magnet itself (4.2 K) is well insulated from the sample chamber in the center of the magnet bore. The probe in which the sample is housed usually incorporates accurate temperature control over a range typically of 4–40 °C for biological samples. The RF coil in the probe is connected in turn to a preamplifier, receiver circuitry, analog-to-digital converter (ADC), and a computer for data collection.

Consideration of Equation (2) provides an insight into some of the RF requirements for NMR spectrometers. Because \(\gamma\) is substantially different for different nuclei, the absolute frequencies of different nuclei are quite different in a given magnetic field. For example, in a 500-MHz (11.7-T) spectrometer, the \(^1\)H frequency is 500 MHz, but the \(^{13}\)C frequency is only 125 MHz and the \(^{15}\)N frequency is 50.6 MHz. This vast range of frequencies, combined with substantially different intrinsic sensitivities, means that it is impractical to simultaneously detect the signals from all nuclear types in a single NMR experiment. Instead, the RF probe and receiver electronics are selectively tuned for detection of a single nuclear type at any one time. The range of frequencies present for a particular nuclear type in a biomolecule depends on the range of different environments for that nucleus, and is reflected in the chemical shift ranges, typically 10 ppm for \(^1\)H or 200 ppm for \(^{13}\)C. These ranges correspond to approximately 5 and 25 kHz, respectively, in an 11.7-T magnetic field, and such frequency bandwidths are readily detected and digitized. Although only a single nuclear type (usually protons) is detected in a single experiment, most modern multidimensional NMR experiments involve the simultaneous excitation of multiple-frequency bands. Thus, NMR instruments have evolved to be multichannel
devices, with several frequency sources and with RF probes that typically contain two double-tuned coils for delivery of RF pulses at $^1H$, $^{13}C$, $^{15}N$, and sometimes $^2H$ frequencies. In addition, the recent advent of methods based on pulsed-field gradients (PFGs) has added to the sophistication of NMR instruments and these methods are particularly important in the multinuclear experiments described in Section 3.3.

NMR was revolutionized in the late 1960s and early 1970s by the development of Fourier transform (FT) methods. In this approach, a high-power RF pulse simultaneously excites a wide range of frequencies (~100 kHz) for a given nuclear type, giving a marked sensitivity advantage over earlier continuous wave (CW) methods, which essentially excite only one transition at a time. Figure 1 shows a schematic illustration of a simple FT experiment in which an RF pulse is followed by acquisition of a time-domain free induction decay (FID). Fourier transformation of the FID results in the conventional frequency-domain spectrum. As a result of the ubiquitous use of FT methods in modern biological NMR studies, spectrometers are typically equipped with sophisticated pulse-programming facilities so that RF pulses of accurately controlled duration, intensity, homogeneity, frequency, and phase can be programmed and applied to the sample via the RF probe. In multinuclear NMR experiments, the single pulse in Figure 1 is replaced by a series of pulses, as seen later.

So far we have discussed the magnet, RF and detection considerations, and FT methods. Another important aspect of modern NMR spectrometers for biological studies is an appropriately large data-handling system. Two-dimensional NMR data sets typically require several megabytes of disk storage, whereas multidimensional data sets may consume more than 40 MB of disk storage per experiment. For the determination of three-dimensional (3-D) structures of macromolecules, 6–12 2-D, 3-D, or four-dimensional (4-D) data sets may be recorded for an individual sample. Data storage and processing requirements are thus significant.

### 1.3 Nuclear Magnetic Resonance in Biological Systems

Biological macromolecules contain only a very limited subset of the elements from the periodic table. In particular, the most abundant elements in proteins, nucleic acids, lipids, and carbohydrates include H, C, N, O, S, and P. All of these elements contain at least one isotope that is magnetically active and hence accessible via NMR. However, in some cases ($^{17}O$ and $^{33}S$), the properties of the nuclei make detection inconvenient or difficult, and in others ($^{13}C$ and $^{15}N$) the natural abundance, and hence sensitivity to detection, is very low. For detection of $^{13}C$ and $^{15}N$ it is usual to work with isotopically labeled proteins. Both $^1H$ and $^{31}P$ are essentially 100% abundant and are the most sensitive naturally occurring nuclei in biological macromolecules. The $^1H$ nucleus is, by far, the most widely applied and is the one detected in most modern biological NMR experiments.

Table 1 provides some frequency and sensitivity information on the nuclei that are commonly used in multidimensional NMR experiments of biological macromolecules. Other nuclei are often used to facilitate multidimensional NMR experiments but play a passive rather than an active role in the experiments. For example, $^2H$ is commonly used to dilute protons in large macromolecules to indirectly increase the sensitivity of various multidimensional experiments by reducing dipolar broadening. Many other nuclei have roles as selective probes. For example, $^3H$ and $^{19}F$ are used as isoteric replacements for protons because their low background levels in macromolecules allow their detection in the absence of interfering signals from other nuclei. However, most experiments involving these or other selective probe nuclei tend to involve simple 1-D or 2-D methods and are not described further here, where the emphasis is on multidimensional NMR. For multidimensional NMR applications, $^1H$, $^{13}C$, and $^{15}N$ are by far the most important nuclei.

In most intact biological systems, macromolecules are present only at very low concentrations, ranging from nano- to micromolar. Thus, in order to best mimic such systems, it is, in principle, desirable to conduct

spectroscopic investigations at rather low concentrations. In general, sensitivity limitations preclude NMR studies at submicromolar concentrations for 1-D NMR experiments or submillimolar concentrations for 2-D or higher dimensional experiments. The additional complication of difficulty, in general, in obtaining gram quantities of biological macromolecules means that most studies are carried out at millimolar concentrations, with 1 mM having become almost the de facto standard for studies of protein solutions by multidimensional NMR methods. In the usual case where water is the solvent, the proton concentration (110 M) in water is typically up to 100000 times higher than that of the solute (1 mM) in these solutions. One of the consequences of the use of FT methods and the need for digitization of the analog time domain NMR signal is that it is extremely difficult to adequately digitize those signals from macromolecular solutes in the presence of such a large water peak. Water-suppression methods are thus critical for multidimensional NMR studies for biological macromolecules.

The earliest and still very widely used approach for suppression of the water signal involves presaturation of the signal with a long RF pulse prior to collection of NMR data. The method is equally applicable to 1-D, 2-D, 3-D, or 4-D NMR experiments. Such presaturation methods require excellent shimming of the magnetic field so the water signal is as sharp as possible, thereby maximizing the efficiency of the applied radiation so that the minimal amount of RF power is used. Too much power for irradiation results in bleaching of adjacent signals and can result in a significant loss of information content, particularly for Hα proton signals.

More recently, the advent of PFG pulses has revolutionized several aspects of multidimensional NMR experiments, including the procedures used for water suppression. The acronym given for a simple, but very effective and widely used, gradient-based method is WATERGATE. The pulse sequence (shown in Figure 2) consists of two gradient pulses that sandwich a selective 180° pulse (or pulse train). The technique is based on the fact that all coherences dephased by the first gradient pulse are rephased by the second, provided that they have experienced the 180° flip. The selective 180° pulse is thus designed so that all coherences of interest are rotated by 180° but the signal at the water frequency is not rotated and therefore not rephased after the second gradient pulse. Water suppression of the order of 10⁴–10⁵ is achieved using this sequence, which can be incorporated into a variety of multidimensional NMR experiments.

![Figure 2](image.png)

**Figure 2** Schematic illustration of the WATERGATE pulse sequence. Typical settings include a gradient pulse width of 1 ms, gradient amplitude 15–20 G cm⁻¹, and τ ∼ 1 ms. The selective 180° pulse often comprises a tailored excitation pulse train (e.g. a 3–9–19 sequence), which excites all frequencies outside the suppression band at the water frequency. This pulse sequence may be incorporated into a range of different 1-D and 2-D NMR experiments. G1 and G2 denote gradient pulses 1 and 2.

### 1.4 Nuclear Magnetic Resonance Parameters and Reference Standards

NMR is unique amongst the various forms of spectroscopy, in that there are so many parameters that can be measured, each providing information about different physical phenomena. Some of these parameters include chemical shifts, coupling constants, relaxation times, nuclear Overhauser effects (NOEs), peak intensities, and line widths. The theory behind many of these parameters is described in earlier articles of this publication, including Chemical Shifts in Nuclear Magnetic Resonance: Parameters, Calculation of Nuclear Magnetic Resonance: Relaxation in Nuclear Magnetic Resonance, General, Scalar Couplings in Nuclear Magnetic Resonance, General, and is hence not described in extensive detail here. However, because some aspects of the parameters have a central bearing on NMR of biomolecules, brief descriptions of the key elements are given below.

#### 1.4.1 Chemical Shifts

Chemical shift defines the frequency at which an individual nucleus resonates and is perhaps the best known and most important NMR parameter. The most important factor determining chemical shifts is the electronic environment surrounding the nucleus and this depends on a number of factors, including local elements...
of structure. Chemical shifts are expressed in units of parts per million and essentially indicate frequency offsets from a reference standard. Tetramethylsilane is the traditional standard of choice for organic applications of NMR but is not soluble in water, the medium used in most biological studies, so a water-soluble derivative, 2,2-dimethyl-2-silapentane-5-sulfonate (DSS), is now widely adopted is to make use of the “σ ratio” method based on the relationship between frequency and γ defined by Equation (1) for a fixed magnetic field strength. The details of this method are described by Wishart et al.\(^9\) Basically, the method involves the use of the following σ ratios for determining chemical shift zero points for heteronuclei: \(^{13}\)C/\(^{1}\)H = 0.251449530, \(^{15}\)N/\(^{1}\)H = 0.101329118. Measurement of the zero point for a single reference compound (DSS) for \(^{1}\)H allows the zero points for other nuclei to be determined, thus saving both time and effort. The σ ratios (which reflect ratios of γ values in Equation 1) are universal and may be used on a variety of commercial spectrometers at any field strength.

The fact that the theory relating structural factors to chemical shifts is still not developed sufficiently to allow definitive predictions of chemical shifts in simple molecules, let alone macromolecules, does not diminish the usefulness of chemical shifts. From the measurements on large numbers of biomolecules, expected ranges of shifts for particular types of environments have been described for many nuclei, including \(^{1}\)H, \(^{13}\)C, and \(^{15}\)N. The “random coil” shifts of \(^{1}\)H nuclei in the 20 common amino acids that make up most protein structures are given in Table 2. This illustrates the general trend that the amide backbone shifts of proteins generally occur around 7–9 ppm, the α protons are in the range 4–5 ppm, and the signals from side-chain protons are typically in the range 0–4 ppm. In structured proteins, considerable variation in the shifts of individual protons from those given in Table 2 is expected but the random-coil values are nevertheless useful in identifying patterns of chemical shifts for different amino acids.

### 1.4.2 Coupling Constants

Coupling constants reflect the splitting of individual resonances that arises from through-bond (scalar) interactions between NMR-active nuclei. Among the applications to biological macromolecules, coupling constants are most valuable for providing dihedral angle constraints in structure calculations. This application owes its origin to the well-known Karplus relationship, originally derived in organic molecules, between three-bond coupling constants (\(^3J\)) and the intervening dihedral angle ϕ (Figure 3). In the case of proteins, the relevant coupling constant is \(^3J_{HNH}\), which defines the ϕ angle in the peptide backbone.\(^1\)\(^1\)

### 1.4.3 Relaxation Parameters \(T_1\) and \(T_2\)

The time constants \(T_1\) (the spin–lattice relaxation time) and \(T_2\) (the spin–spin relaxation time) define the rate of recovery of the nuclear magnetization following a perturbation from equilibrium: \(T_1\) measures recovery
in the longitudinal direction (i.e. in the direction of the magnetic field) and $T_2$ defines the rate in the transverse direction. Both time constants are extremely sensitive to molecular motion and are widely used for the determination of correlation times and amplitudes of internal motions in proteins and nucleic acids. $T_2$ becomes smaller with increasing molecular size, and because it determines the rate of loss of nuclear magnetization it can become a limiting factor in NMR studies of larger molecules. It has an important bearing on the design of some of the complex multidimensional NMR pulse sequences described later in this article.

1.4.4 The Nuclear Overhauser Effect

The NOE was originally noticed as a change in the intensity of one signal in an NMR spectrum upon irradiation of other signals. The effect owes its origin to dipolar interactions between nuclei less than approximately 5 Å apart. Perturbation of the populations of one transition can cause changes in other related transitions, leading to intensity changes in 1-D spectra. In multidimensional NMR, NOEs are manifest as cross peaks in nuclear Overhauser effect spectroscopy (NOESY) spectra, with the intensity of the cross peak proportional to the size of the NOE. The value of NOEs is directly related to internuclear distances and so measurement of NOE cross-peak intensities can be used to derive distance restraints used in the calculation of 3-D structures of macromolecules.

1.5 One-dimensional Nuclear Magnetic Resonance Spectroscopy

The theory of multidimensional NMR, as it applies to macromolecular studies, is best introduced by building on the principles inherent in 1-D NMR spectroscopy, and this is conveniently done with an example. Figure 4(a) shows a typical 1-D spectrum of a medium-sized protein – in this case MiAMP1, a 70 amino acid protein from the seeds of macadamia nuts that exhibits antimicrobial activity. The spectrum is shown to illustrate the strengths and weaknesses of 1-D NMR of biomolecules. The main advantage of such 1-D spectra is that they rapidly allow assessment of the folded state of biological macromolecules. This is usually judged by good dispersion of the amide resonances (7–10 ppm), shifts of $H\alpha$ proton signals upfield (indicative of $\alpha$ helix) or downfield (indicative of $\beta$ sheet) from random coil values, and upfield shifting of methyl resonances – usually an indication of a highly structured environment. These features are evident in the 1-D spectrum of Figure 4(a), but the spectrum also shows the main disadvantage of 1-D NMR of biomolecules – there is extensive overlap of the signals, and assignment of individual peaks in this spectrum is essentially impossible. The need for 2-D or higher dimensional spectra is thus clear.

2 TWO-DIMENSIONAL NUCLEAR MAGNETIC RESONANCE

2.1 Historical Basis of Two-dimensional Nuclear Magnetic Resonance

The original concept of 2-D NMR spectroscopy is widely attributed to a presentation by Jeener at a European summer school in 1971. A formal demonstration of the principles of 2-D NMR was made in 1976. The main advantage of 2-D over 1-D methods is the dispersion of signals into two frequency domains in a way that provides increased resolution as well as fundamental new information on connectivity between peaks. Figure 4(c) shows the relationship between 1-D and 2-D spectra, illustrated with a 2-D total correlation spectroscopy (TOCSY) spectrum of MiAMP1. The diagonal of this spectrum is essentially the 1-D spectrum shown in Figure 4(a), and the off-diagonal or cross peaks are the key features of 2-D NMR spectroscopy. As is probably clear from a brief inspection of the landscape view of the 2-D spectrum in Figure 4(b), it is far more convenient to view the 2-D spectrum in a contour map representation, as shown in Figure 4(c). In contour maps, the intensity of peaks (both diagonal and cross peaks) is represented by the number of contour levels.
MULTIDIMENSIONAL NUCLEAR MAGNETIC RESONANCE OF BIOMOLECULES

2.2 Description of a Generic Two-dimensional Experiment

The theory and applications of 2-D NMR spectroscopy to organic molecules are covered in another article in this publication (see Two-dimensional Nuclear Magnetic Resonance of Small Molecules) and elsewhere, and because the basic principles are the same for small or large molecules we focus specifically on aspects relevant to 2-D, 3-D, and 4-D NMR of biomolecules.

The prototypical 2-D experiment involves a series of RF pulses (at least two) separated by an evolution delay that is incremented in successive steps of the 2-D experiment. In their most general form, 2-D NMR experiments may be thought of as consisting of four successive time periods comprising a preparation period; an evolution period, $t_1$, during which the spins are labeled according to their chemical shifts; a mixing period during which the spins are correlated with one another; and a detection period, $t_2$, where a FID is recorded. This experiment is repeated several times with linearly incremented values of $t_1$ to yield a data matrix $S(t_1, t_2)$. Fourier transformation in the $t_1$ dimension yields a set of $n$ 1-D spectra in which the intensities of the resonances are sinusoidally modulated as a function of the $t_1$ duration. Subsequent Fourier transformation in the $t_1$ dimension yields the desired frequency-domain 2-D spectrum $S(\omega_1, \omega_2)$. In most homonuclear 2-D experiments, the diagonal corresponds to the 1-D spectrum, and the symmetrically placed cross peaks on either side of the diagonal indicate the existence of interactions between spins.

Different types of 2-D experiments are distinguished by the nature of the interactions that are probed during the mixing period. In a correlation spectroscopy (COSY) experiment, the cross peaks arise from through-bond scalar correlations, whereas in an NOE experiment they arise from through-space correlations. The basic pulse sequences for several common 2-D $^1$H-NMR experiments applicable to biological macromolecules are given in Figure 5. It is clear from this figure that an important difference between the experiments lies in the nature of the mixing period, as is further discussed below.
Figure 5  Basic pulse sequences of the double-quantum-filtered correlation spectroscopy (DQFCOSY), TOCSY, and NOESY experiments, illustrating that the nature of the mixing period determines the types of correlations observed in the experiment. Filled rectangles represent 90° pulses; the isotropic mixing (spin lock) pulse is represented by a cross-hatched rectangle; \( t_m \) is the mixing time that allows development of the NOE; \( t_1 \) is the incremented delay; and \( t_2 \) is the detection period. (Adapted from King and Mackay\(^{18} \).

2.2.1 Double-quantum-filtered Correlation Spectroscopy and Exclusive Correlation Spectroscopy

In the double-quantum-filtered correlation spectroscopy (DQFCOSY) experiment,\(^{19} \) the mixing time consists of two 90° pulses separated by a short delay to allow for the switching of RF phases between the second and third pulse in the sequence. The receiver phase and the phase of the final pulse are used to select the magnetization present as double-quantum coherence prior to the final read pulse in the experiment. The DQFCOSY experiment provides information on through-bond connectivities via scalar coupling, and is typically used to obtain spin system assignments and to measure \( ^3J_{\text{H}N\text{H}N} \) coupling constants. This experiment has superseded the basic COSY as the experiment of choice for elucidating these couplings.

In the related exclusive correlation spectroscopy (ECOSY) experiment, phase cycling is used to select only the active couplings from the otherwise complex multiplet.\(^{20} \) The main application of this experiment is to determine \( ^3J_{\text{H}N\text{H}H} \) couplings, which are used to obtain stereospecific assignments, and \( J_{\gamma} \) restraints, which define the orientation of amino acid side chains.

2.2.2 Total Correlation Spectroscopy

The TOCSY (also referred to as homonuclear Hartmann–Hahn spectroscopy) experiment also yields scalar connectivities. In this experiment, the second pulse in the COSY experiment is replaced by a spin-locking pulse (termed the isotropic mixing period) that permits magnetization transfer from one proton to another at a rate determined by their \( J \) coupling.\(^{21,22} \) The high spin-locking field strength (10 kHz) results in an efficient magnetization transfer during the mixing period, and the extent to which magnetization is propagated along a spin system depends on the duration of the spin-locking pulse (typically \( 30–120 \text{ ms} \)). This experiment allows the mutual correlation of all protons within a spin system. This information is very valuable in the assignment of the spectra of proteins, for example, because different amino acids have different numbers of protons at different frequencies (Table 2). As a consequence, cross peaks in TOCSY spectra yield patterns characteristic of individual amino acid types.

2.2.3 Nuclear Overhauser Effect Spectroscopy

In the NOESY experiment, which is based on the NOE, two 90° pulses sandwich an extended mixing time (\( 50–400 \text{ ms} \)) during which the NOEs build up.\(^{23,24} \) During the mixing time, magnetization of one nucleus can lead to variation in the magnetization of another, and the final read pulse detects the modulated signals. Protons mutually exchange their nuclear magnetization at a rate that is inversely proportional to the sixth power of the distance between them, and cross peaks are thus observed between protons that are at a maximum of \( 5–6 \text{ Å} \) apart in space.

2.3 Two-dimensional Nuclear Magnetic Resonance of Biomolecules

Although there are myriad possible 2-D spectra, the assignment of peaks in NMR spectra of peptides and small proteins is usually accomplished with just a handful of experiments; in particular, TOCSY and NOESY spectra are the most important. As mentioned above, the TOCSY spectrum is useful for classifying spin systems into amino acid type, with typically the most useful region being the “skewers” emanating from individual NH shifts, as illustrated in Figure 6, again using MiAMP1 as an example. For each NH proton in the peptide, a series of cross peaks to the \( \alpha, \beta, \gamma, \text{ etc.} \) protons is observed and these patterns define the spin system as belonging to a particular type of amino acid.

In the early days of structure determination of proteins by NMR, the task of classifying peaks into amino acid type was done mainly using DQFCOSY spectra because limitations on hardware at that time made TOCSY spectra technically more difficult to record. Although these hardware limitations have been overcome in modern...
instruments, and TOCSY spectra have principally taken over this role, DQFCOSY experiments are still useful in resolving ambiguities in TOCSY spectra, particularly for the spin systems of longer amino acids and for proline, as illustrated in Figure 7.

Once a reasonable number of amino acid spin systems have been assigned to amino acid type from the TOCSY and DQFCOSY spectra, the NOESY spectrum is inspected to locate adjacent amino acid spin systems. This is done principally by identifying a cross peak between the $\alpha$ proton of one residue ($i$) and the NH of the following residue ($i + 1$), often denoted as $d_{\alpha}N(i, i + 1)$, although support for the assignment is often also observed in $d_{\beta}N(i, i + 1)$ and $dNN(i, i + 1)$ correlations. If the dipeptide pair of adjacent residues identified in this way is unique in the sequence, then the sequence-specific assignment of these residues is complete, and the assignment process continues in a similar manner for the remaining residues. In longer proteins unique stretches of three, four or more residues may need to be identified before a starting point for the sequence-specific assignment is established. The process is complicated by the fact that in a folded protein it is possible that any given $\alpha$ proton may be within 5 Å of more than one amide proton and thus have multiple $d_{\alpha}N(i, j)$ NOEs. Thus, at the early stages of an assignment it is impossible to be certain whether a particular cross peak is a sequential or longer range cross peak, but as the assignment procedure progresses ambiguities get resolved. The assignment process is generally highly convergent in that once a series of correct assignments is made the number of choices for remaining cross peaks diminishes, in principle making their assignment easier.

Once all peaks in the 2-D NOESY spectrum have been assigned, their intensities are used to derive a series of interproton distance restraints. These are then used in a simulated annealing algorithm, together with dihedral angle restraints derived from DQFCOSY and ECOSY spectra to derive a family of 3-D structures consistent with the input restraints.

2.4 Limitations of Two-dimensional Nuclear Magnetic Resonance Methods

As indicated in the previous section, 2-D methods have the advantage of reducing overlap in 1-D spectra and providing additional information in terms of correlations and connectivities between peaks. However, the larger a biological macromolecule becomes, the more protons it contains and hence the higher the probability of overlap. In addition, line width increases with increasing molecular
weight, further magnifying problems of overlap. The net result from both of these factors is that for proteins containing more than approximately 100 amino acids it becomes exceedingly difficult and time consuming to assign spectra and determine 3-D structures from 2-D spectra. Higher dimensional spectra associated with $^{15}$N and/or $^{13}$C, $^{15}$N-labeled molecules are needed.

3 THREE- AND FOUR-DIMENSIONAL NUCLEAR MAGNETIC RESONANCE

3.1 More Dimensions

Higher-dimensionality experiments can be regarded simply as linear combinations of successive 2-D experiments. For example, a 3-D pulse sequence can be constructed from two 2-D experiments as shown in Figure 8. In principle, it is possible to produce combinations of almost any 2-D experiments. This has led to an explosion in the number of techniques available, using both homonuclear and heteronuclear methods. In addition to extending the capacity of NMR for sequential assignment and structure determination as described above, these new techniques have provided an entirely different route to the assignment of protein spectra and have extended the range of NMR spectroscopy to proteins beyond the $\sim 30$-kDa size range.

3.2 Homonuclear Methods

Homonuclear 3-D NMR experiments were amongst the first to be developed. The major advantage compared to their 2-D counterparts is that they offer the possibility to circumvent some of the problems associated with chemical shift degeneracy. Furthermore, by combining a TOCSY (or COSY), which provides scalar correlations, with a NOESY, which gives information on the distance between nuclei, it is possible, in principle at least, to obtain all the information necessary for complete assignment of the protein molecule.

There are a number of problems associated with homonuclear 3-D experiments. Although they offer the potential for improved resolution relative to the corresponding 2-D experiments, they present a number of practical difficulties. The first is in the acquisition of the data. These experiments require the incrementation of two successive delays to produce the 3-D data matrix. As a result of the relatively poor chemical shift dispersion observed for $^1$H nuclei, it is necessary to record a large number of increments to obtain satisfactory digital resolution. Hence, the acquisition times for the experiments can become prohibitively long. Furthermore, because the 3-D experiment contains all the information from the two constituent 2-D experiments, there is a corresponding increase in the number of cross peaks observed, which increases the requirements for good digital resolution. Another potential problem lies in the interpretation of these experiments. The calculation of protein structures from NMR data is critically dependent on the ability to measure a large number of NOEs as accurately as possible. For homonuclear 3-D experiments, the peak volumes are the product of two transfer coefficients, which can complicate the process of extracting accurate distance information for structure calculation. Finally, as is the case with their 2-D counterparts, these experiments are based upon the observation of relatively small $^3$$J$ scalar couplings. Consequently, they only provide useful information for proteins $< 10$ kDa. As a result, homonuclear 3-D methods are less widely used than double and triple resonance experiments that involve the use of uniformly $^{15}$N and/or $^{13}$C-labeled proteins.

3.3 Heteronuclear Methods

The development of recombinant DNA technology has made the production of isotopically labeled proteins relatively straightforward. Thus, it is possible to produce a variety of different protein samples with $^{15}$N and/or $^{13}$C labeling. Both of these nuclei have a spin quantum number $I = 1/2$, which makes them suitable for high-resolution NMR. A variety of labeling strategies are available, ranging from uniform enrichment of either
only or both $^{15}$N and $^{13}$C to selective incorporation of isotope labels for particular amino acids. A major advantage of isotope labeling is that it allows the exploitation of the relatively large short-range scalar couplings that exist between both the heteronuclei and their directly attached protons (Scheme 1). These large couplings result in magnetization transfer between the heteronuclei being very much more efficient than for homonuclear experiments where $^{3}J \approx 3$–$14$ Hz.

The ability to transfer magnetization between heteronuclei is the essential foundation upon which many of the multidimensional methods for resonance assignment and structure determination are based. Although a full mechanistic description of the myriad sophisticated pulse sequences available is beyond the scope of this article, the general principles of heteronuclear magnetization transfer can be outlined in the relatively simple example of an $^{1}$H–$^{15}$N-heteronuclear single-quantum coherence (HSQC) experiment, which correlates the chemical shifts of the $^{15}$N nuclei with those of their attached protons.

A typical pulse sequence for the HSQC experiment is shown in Figure 9(a). The first step of the experiment involves the transfer of magnetization from the $^{1}$H nuclei to $^{15}$N using insensitive nuclei enhancement by polarization transfer (INEPT). There follows an incremented delay, during which the magnetization is labeled with the $^{15}$N chemical shift. Finally, the magnetization is transferred back to the $^{1}$H nuclei, using a reverse-INEPT sequence, and detected. The experiment has very high sensitivity, and Fourier transformation of the data produces a 2-D spectrum with a single in-phase cross peak for each H–N correlation. A typical $^{1}$H–$^{15}$N HSQC spectrum is shown in Figure 9(b).

As is the case with homonuclear 2-D experiments, the HSQC experiment may be regarded as a building block that can be incorporated into more complex multidimensional pulse sequences. Similar heteronuclear magnetization transfer schemes have been described that correlate the chemical shifts of $^{1}$H, $^{13}$C, and $^{15}$N nuclei to facilitate resonance assignment.

Heteronuclear experiments place greater demands upon the spectrometer hardware than homonuclear spectroscopy. Certain experiments require the generation of suitable pulses for excitation of $^{1}$H, $^{15}$N, and $^{13}$C nuclei. For the purposes of the majority of these experiments, aliphatic $^{13}$C nuclei are treated separately from carbonyl $^{13}$C nuclei. Consequently, the spectrometer must possess at least three separate amplifiers (to excite the three separate nuclei), and it must be capable of synthesizing frequency-selective pulses in order to selectively excite the appropriate regions of the $^{13}$C spectrum. Many heteronuclear experiments also use PFGs for the suppression (or selection) of coherences, which requires that the spectrometer have the capacity to produce inhomogeneous RF pulses. Furthermore, in cases where samples have been deuterated, a fourth frequency is introduced and, consequently, an additional amplifier is required. Key developments for multidimensional heteronuclear spectroscopy have included the production of higher magnetic fields, which improves resolution and has important advantages in terms of sensitivity, while improvements in probe technology, notably in the production of shielded-PFG probes, have seen a dramatic improvement in spectral quality.

Scheme 1. Heteronuclear coupling constants (in hertz) found in proteins.
3.4 Heteronuclear-edited Nuclear Magnetic Resonance

The simplest of the heteronuclear 3-D experiments involve the use of the heteronucleus to edit a standard homonuclear experiment. Typically, an HSQC experiment is combined with either a homonuclear NOESY or TOCSY. In general, these experiments are carried out using $^{15}$N as the heteronucleus owing both to its favorable spectral properties and the relatively cheaper cost of producing uniformly $^{15}$N-labeled proteins.

The $^{1}$H–$^{15}$N total correlation spectroscopy/heteronuclear single-quantum coherence (TOCSY/HSQC) separates amide protons according to the $^{15}$N chemical shifts of the attached nitrogen, as is the case with the HSQC spectrum shown in Figure 9(b). In the third dimension there are cross peaks at the frequencies of all proton resonances that have scalar correlations to the amide proton. Thus the 3-D $^{1}$H–$^{15}$N TOCSY/HSQC spectrum consists of “towers” of cross peaks built upon $^{1}$H–$^{15}$N correlations observed in the HSQC experiment containing all of the scalar correlations observed in the amide proton region of a conventional 2-D $^{1}$H–$^{1}$H TOCSY. These spectra are usually displayed as 2-D strips centered at the $^{15}$N chemical shift that contain all of the TOCSY cross peaks for each amide proton, as shown schematically in Figure 10.

The related 3-D $^{1}$H–$^{15}$N NOESY/HSQC spectrum also contains “towers” of cross peaks built upon $^{1}$H–$^{15}$N correlations, but in this case the third dimension contains cross peaks at the frequency of all proton resonances that have dipolar interactions to the amide proton. Using a combination of the 3-D $^{1}$H–$^{15}$N TOCSY/HSQC and 3-D $^{1}$H–$^{15}$N NOESY/HSQC, it is possible to obtain sequential assignments using essentially the same strategy described above for homonuclear 2-D experiments. The advantage of increasing the dimensionality lies in the greater resolution obtained, as illustrated in Figure 10.

Similar experiments can be performed on suitably labeled samples using $^{13}$C as the heteronucleus. Thus the 3-D $^{1}$H–$^{13}$C NOESY/HSQC provides a method for resolving NOEs to protons based on the chemical shift of the attached carbon. In addition to the increased cost of incorporating $^{13}$C labels compared to the incorporation of $^{15}$N.

Figure 10  Schematic representation of the improved resolution afforded by 3-D heteronuclear-edited NMR. The homonuclear 2-D spectrum in (a) contains cross peaks between scalar coupled protons. For larger proteins, lack of signal dispersion often results in resonances becoming overlapped with one another, as depicted in (b). In this case it is no longer possible to distinguish between the three amide protons because they all resonate at the same frequency. However, in many cases the amide proton signals can be separated in an HSQC spectrum according to the resonance frequency of their attached nitrogen, as shown in (c). In this way, overlapping signals in a homonuclear 2-D TOCSY experiment can be resolved in the 3-D $^{15}$N–$^{1}$H TOCSY/HSQC. Correlations to the side-chain protons are observed in the 3-D spectrum at the resonance frequency of the amide nitrogen (d). Such spectra are typically viewed as narrow 2-D strips taken at the $^{15}$N amide nitrogen frequency (e).
of $^{15}$N, there are several reasons why the 3-D $^1$H–$^{15}$N NOESY/HSQC is a more widely used experiment. First, the transverse relaxation rates of $^{13}$C nuclei can be relatively fast, which results in a significant loss of signal. Secondly, both $^{13}$C and $^1$H chemical shifts are closely correlated with secondary structure; thus, it is often the case that the regions of greatest overlap coincide in the two frequency dimensions, which limits the potential gains in resolution. Because there is no correlation between $^{15}$N chemical shift and secondary structure, there is often a correspondingly greater increase in resolution.

For double-labeled proteins, it is also possible to record NOESY spectra that are edited with respect to both $^{13}$C and $^{15}$N. Such an experiment would be a 4-D $^{13}$C–$^{15}$N HSQC/NOESY/HSQC. This experiment further separates dipolar correlations observed in the 3-D $^1$H–$^{15}$N NOESY/HSQC on the basis of the $^{13}$C chemical shifts of the carbon nucleus to which any carbon-bound protons are attached. Effectively, a series of 3-D $^1$H–$^{15}$N NOESY/HSQC data sets are recorded at separate $^{13}$C frequencies. This type of experiment is particularly useful for resolving NOEs between methyl groups in the protein core, where the dispersion is often very poor.

The obvious limitation of the heteronuclear-edited approach to obtaining resonance assignments is that the 3-D $^1$H–$^{15}$N TOCSY/HSQC experiment is based on magnetization transfer via relatively small $^3J$ scalar couplings. Therefore, as is the case with homonuclear 2-D and 3-D experiments, this approach is only successful with proteins $<$10 kDa. Although 3-D and 4-D NOESY/HSQC experiments can be recorded successfully for very much larger proteins, analysis of these data is crucially dependent upon the ability to obtain sequence-specific assignment of the resonances.

### 3.5 Triple-resonance Nuclear Magnetic Resonance

An alternative approach to the sequential assignment problem involves utilizing the one- and two-bond couplings that exist between the heteronuclei and their directly attached protons. These heteronuclear couplings are large in comparison to homonuclear $^3J_{HH}$ couplings. As a result, magnetization transfer between the heteronuclei is very much more efficient than homonuclear scalar transfer. Many experiments that allow magnetization to be transferred between nuclei via scalar couplings have been devised. These multidimensional experiments correlate the chemical shifts of different nuclei, depending on the specific pulse sequence. One such pulse sequence, that of the HNCO experiment, is illustrated in Figure 11. In terms of sensitivity, it is desirable to have the magnetization originate on a $^1$H nucleus and to detect $^1$H signals in

![Figure 11](image-url)  
**Figure 11** Three pulse sequences for the triple-resonance 3-D HNCO experiment. (a) A standard HNCO sequence. (b) A constant-time HNCO. (c) A constant-time HNCO sequence using PFGs incorporating minimal saturation of the water and sensitivity enhancement. In all cases, narrow and wide pulses correspond to $90^\circ$ and $180^\circ$ pulses, respectively, and nonrectangular blocks indicate selective pulses. Periods during which broadband decoupling is applied are indicated.
the direct dimension. In the case of HNCO, there is only one proton involved in the transfer pathway, and it is therefore necessary to adopt a so-called out-and-back approach. Thus $^1H$ magnetization is transferred to $^{15}N$, then on to the $^{13}C$, and back to the $^1H$ via the $^{15}N$. In general, triple-resonance experiments are undertaken on uniformly labeled samples, which makes it necessary for reasons of resolution and sensitivity to refocus the $^{13}C$–$^{13}C\alpha$ interaction during the time that the $^{13}C$ coherence is evolving. Owing to the large chemical shift difference that exists between the $^{13}C$ and $^{13}C\alpha$ resonances, this is easily achieved through the application of appropriate selective 180° pulses at the $^{13}C\alpha$ resonance frequency.

By convention, triple-resonance experiments are named on the basis of the nuclei that are involved in the magnetization transfer pathway. Hence, the HNCO experiment correlates the amide proton $H^N(i)$, the amide nitrogen $N(i)$, and the carbonyl carbon of the preceding residue $C(i−1)$. Nuclei that are involved in the transfer pathway but not frequency labeled are given in parentheses. Thus, the HN(CO)CA experiment correlates the amide proton $H^N(i)$, the amide nitrogen $N(i)$, and the $C\alpha$ carbon of the preceding residue $C\alpha(i−1)$ via the transfer pathway $H^N(i)\Rightarrow N(i)\Rightarrow C(i−1)\Rightarrow C\alpha(i−1)\Rightarrow C(i−1)\Rightarrow N(i)\Rightarrow H^N(i)$, where the $C$ is not frequency labeled. In the names of the pulse sequences, $HN$ indicates that both the amide proton and amide nitrogen are frequency labeled, whereas $CO$, $CA$, $CB$, $HA$, and $HB$ refer to $C$, $C\alpha$, $C\beta$, $H\alpha$, and $H\beta$, respectively. A comprehensive description of all triple-resonance pulse sequences is beyond the scope of this article, although several reviews and monographs that describe many of the commonly used techniques are available. A major advantage of these heteronuclear experiments is that they allow a number of interresidue correlations to be made that provide a direct and unambiguous route to obtaining sequence-specific assignments.

As the number of triple-resonance experiments has multiplied, so have the available strategies for obtaining sequence-specific assignments. The precise strategy employed can be tailored to the molecule being studied, but in general a complementary pair of experiments is recorded, one of which contains only interresidue correlations and the other contains both intra- and interresidue correlations. This general strategy is possible because, as shown in Scheme 1, the amide nitrogen $N(i)$ is coupled to the $C\alpha$ carbons of both the same residue $C\alpha(i)$ and the preceding residue $C\alpha(i−1)$. Thus, when magnetization is transferred from $N(i)$ to $C\alpha(i−1)$ (and conversely from $C\alpha(i−1)$ to $N$) via the carbonyl carbon $C(i−1)$.

Two such complementary experiments are the HNCA and the HN(CO)CA experiments. The HNCA experiment correlates the amide proton and $^{15}N$ resonance with the intraresidue $^{13}C\alpha$ via the $^{1}J_{CN}$ coupling constant and with the $^{13}C\alpha$ of the preceding residue via the $^{2}J_{CN}$ coupling constant, giving rise to a spectrum with two $^{13}C\alpha$ cross peaks for each $^{15}N$ resonance, as shown schematically in Figure 12(a). The HN(CO)CA experiment provides correlations exclusively to the $^{13}C\alpha$...
resonance of the preceding residue by relaying magnetization via the intervening 13C carbonyl. In this case, only a single 13Cα cross peak is observed for each 15N resonance. With a combination of these two experiments, it is possible, at least in theory, to distinguish the intrar residue and sequential cross peaks and to obtain sequential assignments for each of the backbone nuclei. In practice, however, problems with overlapping or missing signals in the spectrum often prevent full assignments being obtained. It is common to begin by recording some of the more sensitive and straightforward out-and-back experiments described above, such as HNCO, HNCA, and HN(CO)CA. Beyond that point the given strategy is often determined by the sample under investigation. In practice, several triple-resonance spectra are usually required, the selection of which is determined by problems encountered during the assignment process.

An alternative approach involves using the HNCACB and the CBCA(CO)NH pair. In these experiments the amide proton and 15N resonance are correlated with the 13Cα and 13Cβ spins of both the same and the preceding residue, as shown in Figure 12(b). Although the HNCACB experiment may contain up to four 13C resonances in each 15N strip, analysis is simplified because the 13Cα and 13Cβ cross peaks are of opposite sign. Furthermore, with knowledge of both 13Cα and 13Cβ assignments, it is possible, in many cases, to unequivocally assign the residue type, which simplifies the subsequent sequence-specific assignment.

Once the backbone resonances have been assigned, it is necessary to record experiments that correlate the side-chain nuclei. Two of the most common experiments for doing so are the HCCH-COSY and the HCCH-TOCSY. These experiments involve transfer of proton magnetization to a directly attached 13C spin, followed by COSY- or TOCSY-type transfer along the carbon backbone. Finally, the magnetization is transferred back to the protons where it is detected. These experiments provide essentially the same information as homonuclear 2-D COSY/TOCSY experiments, but have the advantage that magnetization transfer is modulated by large one-bond couplings, making them useful for the assignment of side-chain resonances in proteins of up to 30 kDa. Furthermore, the addition of the third dimension correlating 13C resonances to their directly attached protons dramatically improves resolution relative to the 2-D experiments. A schematic representation of the data obtained from a 3-D HCCH-TOCSY is presented in Figure 13.

Some of the strategies for obtaining sequence-specific assignments using a pair of triple-resonance experiments are depicted in Figure 14. These experiments have been developed to combat the problems of extensive overlap and large line width that prevent sequence-specific assignments being obtained by homonuclear methods. In general, the assignments are only a starting point in the process of macromolecular structure determination, which requires the unambiguous assignment of through-space NOE interactions. These are obtained using the 3-D NOESY/HSQC and 4-D HSQC/NOESY/HSQC experiments described above.

One of the major problems faced by triple-resonance experiments relates to transverse relaxation, T2. Many triple resonance experiments consist of multiple steps wherein magnetization is transferred between different nuclei via a series of INEPT steps. The signal associated with each nucleus loses intensity over time as a result of a loss of phase coherence, at a rate determined by the T2 value for that nucleus. In the design of triple-resonance experiments, therefore, it is important to minimize the amount of time spent on nuclei that have short T2 values, such as Cα. As shown in Figure 9(a), the INEPT sequence that is used to transfer magnetization between nuclei involves a delay of 1/2J between certain pulses. Thus the duration of the experiment is determined, at least in part, by the magnitude of the appropriate coupling constant for the desired magnetization transfer pathway. An obvious way to increase the sensitivity of any experiment is to reduce the total duration of the pulse sequence, so that less magnetization is lost to T2 relaxation before the signal is acquired. The first triple-resonance experiments, such as the HNCO pulse sequence shown in Figure 11(a), consisted of a magnetization transfer step, followed by a period for frequency labeling. More recently, it has been
shown that these steps can occur simultaneously, which results in much shorter recording times of the so-called constant-time experiments (Figure 11(b)). It is not always the case that modifications that lead to improvements in sensitivity result from a shortening in the duration of the pulse sequence. A more recent HNCO pulse sequence is shown in Figure 11(c). In addition to utilizing PFGs, this sequence employs minimal saturation of the solvent resonance and sensitivity enhancement.\(^{(31)}\)

Most triple resonance pulse sequences are now acquired with the use of PFGs\(^{(32,33)}\). This involves the use of inhomogeneous RF pulses for either the suppression or selection of desired coherences. Prior to the use of PFGs, triple-resonance experiments relied on phase cycling to remove unwanted magnetization. This resulted in the experiments having long measuring times and relied crucially on the spectrometer being highly stable for the duration of the experiments. Using PFGs for

the suppression of unwanted coherences eliminates the need for much of the phase cycling so that in many cases it is now possible to employ two-step phase cycles for many triple-resonance experiments. This means that the measuring time for an experiment is now usually determined by considerations of signal-to-noise for any given sample and experiment and not by the requirements of the phase cycle. An additional advantage of PFGs is that they eliminate unwanted signals in a nonsubtractive manner and provide a straightforward mechanism for cleanly eliminating the solvent signal.

A major driving force in the development of triple-resonance NMR spectroscopy was the necessity to extend the size of macromolecules that were accessible to structure determination. However, larger molecules generally have shorter $T_2$ values, and hence give broader lines. There are two principal contributions to the line broadening observed for larger molecules. The first is due to the fact that for larger molecules a greater proportion of the sample is tumbling at the zero-quantum frequency where it can induce spin exchange and thereby contribute to dipole–dipole relaxation. Secondly, the chemical shift of a particular nucleus is dependent upon its orientation in the magnetic field. When a molecule tumbles rapidly in solution, the chemical shifts of all the different environments are averaged to give an “isotropic” chemical shift. The amount of variation in chemical shift with orientation is referred to as the chemical shift anisotropy (CSA). As the molecule tumbles more slowly, the oscillating magnetic field associated with the CSA can also induce transitions that lead to an increase in the rate of relaxation.

Several methods that attempt to minimize signal loss due to $T_2$ relaxation are available. Incorporation of deuterons into the protein is being widely used to extend the applicability of multidimensional NMR to larger systems. A deuterium nucleus has a much lower magnetogyric ratio than the proton and therefore it contributes far less to dipole–dipole relaxation. Even partial deuteration of a protein sample results in significant improvements in $T_2$. Different strategies for protein deuteration have been proposed, involving either partial or full deuteration, but the overall effect is a drastic reduction in the dipolar broadening of resonances, owing to the removal of a large number of protons. More recently, further sensitivity gains have been accomplished by the development of transverse relaxation-optimized spectroscopy (TROSY). This approach utilizes the finding that at a particular field strength the CSA and dipole–dipole relaxation can be canceled out. This generates one component of the observable signal in the HSOC spectrum that essentially has very little $T_2$ relaxation. Using the combined approach of protein perdeuteration and TROSY techniques, spectra have been recorded on protein complexes in the range of 1 MDa.

In addition to increasing the molecular-weight range of molecules that are amenable to structure determination using NMR, triple-resonance experiments allow the measurement of a number of parameters that may be used directly in the structure calculation and refinement. The most obvious are the chemical shifts of the heteronuclei that are determined. Chemical shifts have been used widely to identify elements of secondary structure in proteins. More recently, $^1$H and $^{13}$C chemical shifts have been included as refinement terms in protein structure calculations. In addition, the incorporation of heteronuclei allows the measurement of many more scalar couplings than that possible in homonuclear spectra. Heteronuclear coupling constants provide torsion angle information that may also be used in structure calculations.

Both chemical shifts and coupling constants, like the NOE, contain information only about the local conformation of a macromolecule. Two additional parameters that may be obtained for isotopically labeled samples provide long-range information that can be used to calculate the relative orientation of separate domains even in cases where few short-range interactions exist. The first of these involves the measurement of residual dipolar couplings. In cases where macromolecules tumble anisotropically, the dipolar interaction between pairs of spins, which is related to the angle between the vector joining the spins and the externally applied magnetic field, is not averaged to zero. This results in the observation of small splittings in the spectra of dipolar coupled nuclei. The size of the observed splittings is related to several factors, including the strength of the applied magnetic field and the degree of anisotropy. In practice, dipolar couplings are often measured under conditions that induce alignment (and hence anisotropy), such as solutions of magnetically aligned bicelles or filamentous bacteriophages. The relationship between the size of the splitting and the angular orientation of the dipole vector enables the relative orientations of structural elements within the protein to be established. The second method relies on measurement of heteronuclear relaxation parameters $T_1$ and $T_2$. In molecules that tumble isotropically, the $T_1/T_2$ ratio is constant. However, molecules that tumble anisotropically display angular dependence of the $T_1/T_2$ ratio. Again, this allows the relative orientations of discrete domains in macromolecules to be determined.

### 3.6 Limitations and Future Developments

Recent developments in multidimensional heteronuclear experiments, as well as improved strategies for isotope...
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

labeling.\(^{(45)}\) have extended the scope of macromolecular NMR to larger biomolecules, and structural studies on proteins with molecular weights of up to 30–40 kDa are becoming routine. Furthermore, additional information available from heteronuclear spectra has improved the precision and accuracy with which macromolecular structures can now be calculated from NMR data. There are also some examples of very much larger systems where structural information has been obtained.\(^{(35,46)}\) In addition to the structural information, NMR spectroscopy continues to provide a unique method for the study of protein dynamics. There are now several examples where NMR has been used in conjunction with other techniques to provide clearer insights into motions over a range of timescales, and it is becoming increasingly clear that flexibility plays a key role in the function of many proteins.\(^{(47–49)}\)

An emerging area is the application of NMR spectroscopy to the study of intrinsically unstructured proteins.\(^{(50)}\) Typically, these systems have very poor signal dispersion, which makes the process of obtaining sequential assignments more challenging. In principle, the problem of overlap can be reduced by increasing the dimensionality of an experiment, but this comes at the cost of increased requirements on spectrometer recording time. Recently, a number of schemes have been developed to address this problem.\(^{(51,52)}\) These projection–reconstruction methods allow for rapid acquisition of high-dimensionality experiments, which would otherwise have prohibitively long acquisition times. Recently, a six-dimensional experiment acquired using automated projection spectroscopy (APSY) that allows full backbone assignments from a single experiment was reported.\(^{(53)}\) The peak lists generated in such experiments are very accurate, which makes the assignment process amenable to automated analysis.\(^{(54)}\)

Collectively, these new tools extend the scope of NMR spectroscopy to a wider range of biomolecular systems, increase throughput, reliability and, ultimately, the quality of the data that can be produced. These advances have made NMR spectroscopy an invaluable tool for the study of protein structure and protein dynamics in a number of structural biology and structural genomics programs.

The nuclear magnetic resonance (NMR) spectrometer consists of a superconducting magnet, a sample probe, a radio-frequency (RF) transmitter, a receiver, and a computer for instrument control and data processing. The superconducting magnet provides an ultrastable magnetic field in the central volume of the magnet. To maintain the current, the solenoid that produces the field is immersed in liquid helium to maintain the superconducting state. Surrounding the magnet volume is a set of vacuum jackets and a liquid nitrogen–filled volume to isolate the low-temperature regions from room temperature. The magnet has a bore to house the sample probe and a room-temperature shim (RTS) coil assembly to reduce inhomogeneity of the magnetic field across the active sample volume. The sample to be analyzed is usually dissolved in a deuterated solvent and is contained in a specially ground glass tube that is inserted into the volume of the probe coil. RF pulses, from one or a set of high-power transmitters, are applied to the sample through the RF coil that surrounds the active sample area to perturb the sample. The RF pulses are controlled to ensure precise frequency, phase, duration, and amplitude of the RF voltage. The response of the sample is gathered by recording the induced voltage across the RF coil. The response (the signal) is digitized as a so-called free induction decay (FID) with a high-performance RF receiver including a preamplifier, an amplifier, and an analog-to-digital converter (ADC). By using Fourier transformation (FT), the time-domain FID is converted into the frequency-domain spectrum, often known as the NMR spectrum.

1 INTRODUCTION

NMR spectroscopy has a wide range of applications in chemistry, pharmaceuticals, proteomics, structural biology, structural genomics, metabolomics, and materials science and engineering, where it is used to identify structural features of the molecules in a sample. It is a powerful analytical tool for quantitative and qualitative characterization of these molecules. Because of the wide range of problems that analysis by NMR can address, NMR spectrometers are found in industrial, academic, and government laboratories around the world, wherever identification and quantification of the components of a sample are important.

The NMR signal arises from interactions between the magnetic moments of nuclear spins and the applied external magnetic field (see Zeeman Interaction in Nuclear Magnetic Resonance). The NMR spectrometer is used to detect these NMR signals, the interpretation of which yields important structural and dynamic information. The traditional information obtained from the NMR spectrum is the various interactions of nuclear spins with environment, such as chemical shifts, scalar coupling, and relaxation rates. For certain nuclei with nuclear spin $I > 1/2$ the magnitude of the quadrupolar coupling can also give information on the local electronic state (see Quadrupole Couplings in Nuclear Magnetic Resonance, General).
When a collection of NMR-active nuclear spins (which we consider here to have \( I = 1/2 \)) is placed in a strong static magnetic field \( B_0 \), the magnetic moments, \( \mu \), associated with the nuclear spins precess about the direction of the magnetic field. The precession frequency is known as the Larmor frequency, \( \omega_0 \), of the nucleus. If the magnetic moment is not directed along the magnetic field, it has two components, the projection along the field and the projection along the plane perpendicular to the field. The precession about the field causes this latter component to be time dependent.

After a sample has remained in a field for a time sufficiently long to establish equilibrium, (see Relaxation in Nuclear Magnetic Resonance, General) the collection of spins shows the following two qualities: (i) there is a finite magnetization aligned with the magnetic field and (ii) there is no net magnetization perpendicular to the field. The first of these phenomena is understood by the fact that there are two states with projection along the field, either parallel (\( \alpha \)) or antiparallel (\( \beta \)). The population of \( \alpha \) nuclear spins is slightly greater than that of \( \beta \) spins because of a slightly lower energy associated with \( \alpha \) nuclear spins. The second is a result of the fact that the precession of each of the individual moments occurs in such a way that the various spin moments have incoherent phase. The Larmor frequency, \( \omega_0 \), which is the nuclear precession frequency in the applied external magnetic field expressed in radians per second, is proportional to the strength of the external field:

\[
\omega_0 = \gamma B_0
\]

where \( \gamma \) is the magnetogyric ratio of the nucleus being observed, and \( B_0 \) is the magnetic-field strength in tesla. When the Larmor frequency is expressed in units of cycles per second (Hz), we have \( \nu_0 = \gamma B_0/2\pi \). For a magnet with a field of 14.09 T, the nominal Larmor frequencies of \(^1\text{H}\) and \(^{13}\text{C}\) are 600.0 and 150.9 MHz, respectively. For this reason, besides quoting the magnetic-field strength in tesla, it is common parlance to specify the field strength of an NMR spectrometer in terms of the \(^1\text{H}\) Larmor frequency. It also happens that the Larmor frequency is directly proportional to the energy difference between the two states:

\[
\Delta E = \hbar \omega_0
\]

where \( \hbar \) is Planck’s constant divided by \( 2\pi \). Thus, a measure of the Larmor frequency is a measure of the energy spacing between the two stationary states of a spin. For example, for a 600 MHz magnet at 300 K, the energy difference, \( \Delta E \), is \( 3.97 \times 10^{-25} \) J for \(^1\text{H}\) nuclei. This small energy difference results in a very small population difference between the two levels at room temperature. The induced voltages (the NMR signal) are therefore quite small, even at the highest achievable magnetic fields. This fact makes NMR spectroscopy a relatively insensitive technique, when compared to other spectroscopic methods such as infrared or optical spectroscopy. Because of this issue, the majority of developments in NMR instrumentation focus on various means to increase the sensitivity of NMR measurements.

Since the Boltzmann factor that determines the magnitude of the NMR signal is proportional to the externally applied field \( B_0 \), higher magnetic-field strength leads to higher sensitivity in the NMR experiment. The additional benefit of higher field is that, at higher frequencies, the natural noise in the detection circuits (including the NMR probe, receiver, and amplifiers) is lower, so that the signal-to-noise ratio (S/N) increases faster than linearly with the magnetic field. In recent decades, we have seen a continual development of higher and higher magnetic fields for use in NMR spectroscopy.

A second practical reason for the use of higher magnetic fields follows directly from quantum mechanical consequences of the direct dependence of the magnitudes of various couplings on magnetic field. The two couplings that are the “bread and butter” of NMR are the chemical shift and the scalar, or \( J \), coupling (see Chemical Shifts in Nuclear Magnetic Resonance: Scalar Couplings in Nuclear Magnetic Resonance, General). What makes NMR such an important technique is that nuclei in different local environments have precession frequencies (and hence energy spacings) slightly different from the nominal Larmor frequency. The measurement of all of these frequencies, reported as chemical shifts, specifies the local structure of the molecule in which the spins are embedded. The chemical shift range expressed in hertz is proportional to the applied magnetic-field strength, \( B_0 \). Thus, at higher fields, two resonances are separated by a larger frequency difference than they would be at lower field. On the other hand, the spin–spin coupling is independent of field. Thus, at higher field, the chemical shift difference between two resonances becomes relatively larger than the \( J \) coupling. The form of the NMR spectrum depends on the relative size of the \( J \) coupling and chemical shift difference between the two resonances. In particular, when the \( J \) coupling is much smaller than the chemical shift difference, the form of the spectrum becomes quite simple. Thus, evaluating a spectrum at high field guarantees a simpler spectrum than one acquired at lower field.

For spins other than \( 1/2 \) there is an additional effect, the quadrupolar coupling, to electric field gradients that can affect the spectrum. This interaction is independent of field strength, so carrying out experiments at higher magnetic field provides, in some cases, a simplification of the NMR spectrum. Therefore, there are several reasons to develop higher magnetic fields for NMR spectroscopy or to use the highest possible magnetic field for studies.
As mentioned above, the equilibrium condition is such that the sample has a macroscopic magnetization that lies along the magnetic field, with no macroscopic magnetization perpendicular to the magnetic field. A common way to measure the precession frequencies is to place magnetic moments perpendicular to the main magnetic field so that they precess about its direction. This strategy employing the transverse magnetization allows one to record magnetic fields in the sample that are many orders of magnitude smaller than the main static fields. One may create this transverse magnetization by applying appropriate bursts of RF energy to the sample, after which the sample acquires a macroscopic magnetization perpendicular to the main field direction for a finite amount of time. The RF burst (called a pulse) must have a carrier frequency close to the frequency of precession of the nuclear spins; it must be reasonably strong; and it must produce a coherent time-dependent magnetic field, $B_1$. An RF current through a solenoidal coil (or coils in some geometries) produces a $B_1$ field along the axis of the solenoid; if the current is time dependent, the magnitude of the field is also time dependent. The application of such a field (oriented perpendicular to the main field) to a system initially at equilibrium in the main field results in the creation of magnetization perpendicular to the main field. If the time of excitation is sufficiently short (i.e. the excitation is a short pulse), the transverse magnetization at the end of the RF pulse will be coherent and will subsequently precess about the main field at a frequency characteristic of its particular environment, as determined by interactions such as the chemical shift and $J$ coupling. The RF pulse may produce various effects, depending on the amplitude, the RF phase, and the carrier frequency, so these parameters must be precisely controlled to make the greatest use of a modern NMR spectrometer.

Let us introduce a bit of nomenclature. If the magnetization is allowed to rotate $90^\circ$ from its equilibrium position along the external magnetic field (or z axis) during the pulse, the RF excitation is referred to as a $90^\circ$ pulse. If the magnetization is allowed to rotate $180^\circ$ during the RF excitation, the pulse is said to be a $180^\circ$ pulse, and so on. In addition, the relative phase of the RF excitation is important. Relative to some coordinate system, the $B_1$ field may fall along the x axis or the y axis, or any other axis in the transverse plane. Generally, the x and y directions (and sometimes the $-x$ and $-y$ directions) are the most important, and so the pulse is called an $x$ pulse or a $y$ pulse, with symbols $90^\circ_x$ and $90^\circ_y$, respectively. The phase of the pulse indicates the Cartesian axis around which the magnetization is rotated and, hence, where the magnetization ends after the $90^\circ$ pulse. An $x$ pulse puts the magnetization initially parallel to the $y$ axis, whereas a $y$ pulse puts the magnetization along the $-x$ axis. It is important to realize that the sense of rotation is arbitrary; by convention a right-hand Cartesian axis system is chosen; however, the rules can be reformulated for left-hand rotations, with equivalent results.

Following a $90^\circ$ RF pulse, the net magnetization, being perpendicular to the field, precesses at the Larmor frequency around the direction of external magnetic field. This motion of the magnetization induces a time-dependent voltage in the probe coil, which can be detected and digitized as a function of time, which is the FID. FT of the time-domain FID produces a frequency-domain NMR spectrum that contains all the frequency components of the magnetization. From the frequency spectrum, the analyst can determine the presence or absence of certain types of nuclei and certain types of chemical environment. Aside from this simplest NMR experiment, the control of pulses allows one to perturb the magnetization’s evolution by a variety of other experimental protocols to provide selective information on couplings and kinetic constants.

In an NMR spectrometer designed for detection of nuclei in liquid samples, there are usually several RF systems operating simultaneously, generally at different frequencies. These are termed channels of the spectrometer. In addition to the channel employed for detection of the desired nucleus (the observe channel), one channel is usually dedicated to the detection of the deuterium signal from the deuterated solvent (e.g. CDCl$_3$) in which the sample is dissolved. This channel is often referred to as the lock channel because the corresponding signal is used for the purpose of controlling the long-term stability of the magnetic field. The number of additional RF channels depends on the configuration of the spectrometer, and that in turn is dictated by the kinds of experiments being done on the spectrometer. For most routine analytical NMR spectrometers, besides the lock channel, there are two observe RF channels, one for high-frequency $^1$H detection and another for multinuclear detection usually at lower frequencies, with the capability of providing any frequency over a wide range. This channel is often labeled the broadband channel. In addition, many experiments require decoupling of some nuclei (often protons), so the high-frequency channel may also be known as the decoupling channel. For high-end biomolecular NMR research spectrometers, there are at least three observe channels ($^1$H, $^{13}$C, and $^{15}$N) because of the need to carry out highly sophisticated multiple-frequency experiments. Modern instruments usually have equivalent broadband transmitters for each channel, while the amplifiers dedicated to different nuclei may be different (e.g. $^1$H amplifier has a unique high-frequency configuration, with the low-frequency broadband amplifiers used for the remaining channels being the same).

It should be obvious from the short discussion above that the NMR spectrometer requires the following: (i) a strong, stable, and highly homogeneous magnet, (ii) a
probe circuit that houses the sample and has a coil, often a solenoid, to which RF voltage is applied to produce the perturbing field, (iii) a set of RF amplifiers to generate the RF voltages (pulses) applied to the coil, (iv) an RF receiver capable of detecting the tiny voltages generated by the precession of the nuclear magnetization, (v) a system to perform the detection (which usually involves some demodulation, amplification at a lower frequency, the necessary devices to transform the analog voltages into digital data, and some means of storage), and (vi) a number of computers with special software to control all aspects of spectrometer RF pulsing, data acquisition, and processing.

After a brief discussion of the history of, and the current state of the art in, NMR instrumentation, each part of the NMR spectrometer is described in more detail. Since our laboratory is mostly equipped with Bruker BioSpin instrumentation, the Bruker NMR spectrometer is used as an example to illustrate the concepts and architecture of the NMR instrumentation in the following sections. Similar descriptions could be made of laboratories employing other NMR spectrometers (e.g. Varian, JEOL, or Tecmag), although the details of analysis, processing, and setup may be slightly different. A general procedure to operate a solution NMR spectrometer and to acquire an NMR spectrum is given. Finally, the future perspective in the development of NMR instrumentation is discussed.

2 BRIEF HISTORY OF NUCLEAR MAGNETIC RESONANCE INSTRUMENTATION

Since the first detection of NMR signals in bulk materials independently by Bloch et al.\(^1\) and Purcell et al.\(^2\) in 1946, NMR instrumentation has evolved rapidly and continuously for more than 60 years. Early NMR experiments were carried out with permanent magnets or electromagnets. In those days, the magnetic field was slowly swept over a region with an RF field constantly impinging on the sample. When the resonance condition of Equation (1) was encountered, the response was observed as a change in the quality (Q) factor of the coil. Thus, early spectrometers (known as continuous-wave (CW) spectrometers) produced a plot of the Q factor of the coil as a function of the field, the Q factor of the coil being a measure of the absorption of energy by the sample. In principle, one could sweep the frequency while holding the field constant, and that was indeed done by some groups. It was, however, more difficult to sweep the frequency of the excitation field, so the majority of spectrometers at that time were of the field-swept variety.

The first commercial NMR spectrometer with a permanent magnet running at the \(^1\)H resonance frequency of 30 MHz was pioneered by Varian in 1952. It was a field-swept spectrometer. Already, the trend toward building magnets with higher fields was evident. By the early 1960s, electromagnets with field strengths up to 100 MHz were commercially available. In general, these spectrometers could detect only the resonance of a single nuclear species, usually the proton.

In the mid-1960s, the first superconducting magnet was introduced by Varian.\(^3\) The superconducting solenoid magnet, much more stable than electromagnets, provided magnetic-field strengths unattainable with electromagnets. This resulted in an overall increase in sensitivity. In addition, because at higher fields one could still attain the same magnetic-field homogeneity, the resolution of the NMR measurements was greatly enhanced by the use of the superconducting magnets.

At about the same time that superconducting magnets became available, the demonstration\(^4\) of the Fourier transform relationship between the FID and the frequency spectrum and the development of fast Fourier transform (FFT) paved a new path for NMR spectroscopy. The combination of the detection of the time response and the superconducting magnet added another dimension to the NMR experiment. Because of the ultrastability of superconducting magnets and the exact repeatability of the time response, signal averaging (which had been done only occasionally in swept-mode systems) became commonplace. One year after the demonstration of the technique, the first FT NMR with a superconducting magnet was marketed.\(^5\) The FT experiment is generally repeated in a few tens of seconds, rather than the many minutes it took for acquisition of a single CW spectrum, and allowed a dramatic increase in the S/N within a given time. This added the real possibility of detecting nuclei like \(^{13}\)C with routine spectroscopy, and soon multinuclear spectroscopy became a part of the analytical toolbox.

Of equal importance has been the fact that excitation sequences were developed to parse or factor the information in a spectrum. For example, the utilization of RF-pulse sequences has resulted in multidimensional NMR techniques, from which rich structural information is easily extracted.\(^6,7\) These multidimensional NMR experiments have become part of routine experimental protocols and are now offered as a standard component of any NMR spectrometer software package.

Since its introduction, the superconducting magnet has been one of the driving forces behind modern NMR spectroscopy. The magnetic-field strength attainable by the highest-field commercial superconducting magnet has increased roughly linearly from a Varian 200 MHz spectrometer in 1966 to a Bruker BioSpin 950 MHz spectrometer in 2006.\(^5\)

Developments in probe technology also greatly expanded the utility of NMR over the years. In early
studies, the probe circuit was tuned for a single nucleus (usually $^1\text{H}$) and the response of the $^1\text{H}$ was monitored with all the interactions that naturally affect the proton being seen in the structure of the spectrum. Over the years, probes have evolved from a single-channel type to those that contain multiple RF channels to accommodate the excitation and detection of several nuclei simultaneously. Early multichannel probes had to be tuned manually, which is a time-consuming operation. Modern probe design and computer control allow fully automatic tuning and matching (ATM) of several different simultaneous circuits. This automatic operation has produced an open-access laboratory environment, where the experimenter does not have to delve into the eccentricities of RF electronics to obtain usable NMR spectra. Recently, the development of cryogenically cooled probes has led to a leap in sensitivity owing to noise reduction in the probe electronics.

In the wake of the rapid development of digital electronics, extensive digital control of the spectrometer is common nowadays. This also simplifies the adjustments that were necessarily made by operators with older analog (or partially analog) spectrometers. Needless to say, the rapid developments in computer technology quickly become incorporated into NMR spectrometers.

3 CURRENT STATE OF THE ART IN NUCLEAR MAGNETIC RESONANCE INSTRUMENTATION

A typical twenty-first-century state-of-the-art NMR spectrometer is shown in Figure 1. An actively shielded superconducting solenoid produces a 600 MHz magnetic field (A). The magnet is mounted on antivibration posts (B) to isolate low-frequency (<25 Hz) building floor vibrations that might affect the NMR spectroscopy. Floor vibrations can be easily observed as satellite peaks appearing around the main resonance peaks in a high-resolution NMR spectrum. With reasonable magnetic-field homogeneity, the intensities of floor vibration peaks can be reduced to less than 0.55% of the main peak intensity.

The RF generators, amplifiers, receivers, lock channel, pulsed-field-gradient (PFG) amplifiers, and other spectrometer control units are mounted inside the spectrometer console (E). In a basic configuration, there are three RF channels including one for $^1\text{H}$, a second for other (sometimes called $X$) nuclei (i.e. $^{13}\text{C}$, $^{15}\text{N}$, $^{31}\text{P}$ . . .), and the third for the deuterium lock that regulates the magnetic field. The RF pulses are created by a computer-controlled pulse program. This computer program controls precisely the frequencies and the timing of the RF pulses. Frequency generation and timing of RF pulses are carried out digitally to produce pure frequencies. The digital pulse instructions are converted into analog waveforms that are brought to the appropriate power level by the RF amplifiers, which are linear over a wide range (<120 dB) and capable of producing several hundred watts of RF power. Modern receivers are completely digital and use oversampling technology to eliminate artifacts related to the digitization process.

The $^2\text{H}$ lock channel is also digitally controlled by its own microprocessor to compensate for any field drift and to maintain field homogeneity through adjustment of the RTS coils. The primary computer (D) provides a graphic user interface (GUI) that allows the spectrometer operator to set up a pulse program, control experimental progress, and process the acquired data.

The type of probe in a particular system depends on the type of research for which the spectrometer is used or the role that the NMR spectrometer serves. In Figure 1, the cryogenically cooled probe (mounted inside the magnet) is controlled by a cryocooling unit (C). Other multiple probe configurations are available commercially. The most popular configuration for routine use in analytical solution NMR is a 5-mm inverse broadband probe with PFG capability. Another useful probe for routine service is the so-called quad nuclei probe, which is pretuned for four different nuclei, with ease of switching among the channels by digital commands. These probes are readily used for acquiring data in one-dimensional (1-D), two-dimensional (2-D), and three-dimensional (3-D) NMR experiments without the necessity of changing cabling or retuning the probe.

The architecture of modern NMR spectrometers is modular, which makes expansion of the spectrometer functionality relatively simple. The addition of a sample changer or other automation accessories and the associated control software makes a routine open-access spectrometer that can be easily operated by users having only had a brief basic training. An additional RF amplifier and transmitter (e.g. $^{15}\text{N}$) can be added.
to the basic spectrometer to extend the capability for analyzing biological samples. In addition, many types of cryogenically cooled probes are available for the enhanced sensitivity required in experiments such as the detection of natural-abundance $^{15}$N, the $^{13}$C 2-D INADEQUATE (incredible natural-abundance double quantum transfer experiment), the $^{13}$C measurement of polymeric materials at high temperature, and triple-resonance ($^1$H, $^{13}$C, $^{15}$N) experiments that are essential to analysis of biological macromolecular samples. When equipped with a high-power amplifier, a solid-state probe, and a magic-angle spinning (MAS) controller, the modern NMR spectrometer can readily analyze solid materials.

NMR spectroscopy has also become an integral part of many hyphenated analytical techniques such as liquid chromatography/nuclear magnetic resonance (LC-NMR) (see High-performance Liquid Chromatography Nuclear Magnetic Resonance). These techniques find a great deal of use in the pharmaceutical and chemical industries, where effective separation and structural elucidations may be carried out in a single apparatus. The mixture separated by liquid chromatography (LC) is routed to the NMR spectrometer where the individual pure components of the mixture are injected individually into a flow NMR probe to be analyzed.

Further developments even combine LC, NMR, and mass spectrometry into a liquid chromatography/nuclear magnetic resonance/mass spectrometry (LC-NMR/MS) system. Such systems are valuable because it is often desirable to have multiple means of analyzing some samples. A commercially available integrated system allows the use of an NMR spectrometer and a time-of-flight (TOF) mass spectrometer to give both analyses of a sample. This technology is an ideal platform for metabolomic studies.

The use of solid phase extraction (SPE) provides an efficient interface between LC and NMR when demanded for special flow probes. The liquid chromatography-mass spectrometry (LC-MS) provides the exact mass of the analyzed sample and access to the sum formula. The combination of these three powerful techniques often gives the answer to a question in a matter of minutes.

The ubiquity of nuclear magnetic resonance spectroscopy, especially its wide applications to analysis of chemicals in the laboratory or in the factory, has created an industry catering to the needs of NMR spectroscopy. Companies specialize in the production of NMR solvents, or in specifically isotopically enriched materials for use in studies that focus on a particular site (such as in studies of enzymes). Some companies specialize in consumables such as NMR tubes. Finally, the development of NMR software for specific applications is yet another niche market that is serviced by a number of companies. Readers are referred to the website http://www.ebyte.it/library/NmrMriCompanies.html for a constantly updated directory of NMR and magnetic resonance imaging (MRI) companies.

4 DESCRIPTION OF NUCLEAR MAGNETIC RESONANCE SPECTROMETER

A modern NMR spectrometer consists of a superconducting magnet, including a cryoshim coil assembly to compensate for the inhomogeneity of magnetic field, an RTS coil assembly to adjust the magnetic homogeneity variations between the different samples, a sample probe, transmitter channels including a lock channel, an RF receiver system, and a computer. In addition, there may be a subsidiary slave acquisition computer (AC) for controlling the RF transmitters, which is addressed by the primary computer. A schematic diagram of an NMR spectrometer is shown in Figure 2. The primary computer (A) serves as an interface between the spectrometer operator and all the components of the spectrometer. The operator’s instructions are interpreted by the primary computer and are transferred to an AC through an Ethernet cable (B). From the AC, all incoming information is routed to appropriate devices through a data bus or through RS-232 or RS-485 serial lines. The information returned to the AC, such as variable temperature-control output, lock signal, shimming responses, and other control signals are transferred back to the primary computer through the Ethernet cable (B). The time-critical information such as pulse timing and frequency control are sent back and forth from the AC to the appropriate control boards through a high-speed data bus. Signals that are not time critical (shim, lock, and variable temperature control) are transferred through an RS-232 or RS-485 cable. Most recently, the RS-485, which is faster than RS-232 and can be used to control several units simultaneously, has been used for communication to the preamplifiers and signal-generation units.

All NMR experiments start with a sequence of instructions for RF puling, delays, and data acquisition. The pulse sequence, entered by the operator at the primary computer, is transferred to the AC as the instructions for the synthesizer to produce RF signals with a specific frequency near the Larmor frequencies of the nucleus being studied. All RF events are synchronized to the same clock. The digital RF signal instructions are converted into analog commands (voltages) that can drive the RF amplifiers. The output voltage sequence of the RF amplifiers (ranging from milliwatts for decoupling to hundreds of watts for excitation) is applied across the probe coil to produce the RF magnetic field that excites the sample.

At appropriate times, the probe coil is also used as a detector of the NMR signal. The resulting induced
voltage is amplified by an RF preamplifier. The amplified signal is fed to the receiver section, which includes a reference mixer to reduce the frequency of NMR signal from the RF region to the audio frequency region. At this point, the signal is often amplified with an audio amplifier. The analog voltage is then digitized. Prior to digitization, a digital noise reduction filter is often used to remove aliased signals and noise. The digitized signal is then stored in the principal computer. When the experiment is repeated, the data are coadded and stored in the principal computer.

If the spectrometer is equipped with a gradient accessory for destruction of undesired magnetization remaining between repeated scans, gradient-pulsing control is carried out by the same computer, so that RF and gradient control are synchronized. As shown in Figure 2, the lock channel (F and H) can be considered as an independent $^2$H spectrometer parallel to the observe and decoupling channels.

Subsequent to data collection, the digitized signal (the FID) is transferred to a frequency-domain spectrum using the FFT algorithm by the primary computer. At this point, digital manipulation of the FID is possible, for example, with various apodization procedures. An example of FFT is given in Figure 3, where the time-domain FID is on the left and the frequency-domain spectrum is on the right.

The exponential decay of the FID signal results from nuclear relaxation processes.

4.1 Superconducting Magnet

An ultrastable strong magnet field in the active sample volume is provided by a solenoid made of alloys generally containing niobium, which are superconducting at the temperature of liquid helium. A schematic diagram of a superconducting magnet is given in Figure 4. The intense static magnetic field is the result of the constant current in a coil of superconducting niobium-alloy wire that comprising the magnet (F). The wire must be immersed in a bath of liquid helium (\(\leq 6\) K) (D) to keep it in superconducting state. In the superconducting state, the electric current running through the magnet coil is said to be persistent, in that there are no losses of current due to resistive effects. Besides the main coil, a set of cryoshim coils also in the superconducting state is provided to create small fields to offset inhomogeneities in the main field. Once set, the currents in all the superconducting coils remain constant and are not generally changed by the user. To reduce the boil-off of liquid helium, it is encased in a vacuum jacket packed with materials that limit radiative losses. This setup is surrounded by a further jacket (E) filled with liquid nitrogen (77 K) and another vacuum jacket (C) to isolate it as much as possible from the room-temperature environment. The central bore of the magnet, which houses the sample probe, is at room temperature.

At the time of installation of the NMR spectrometer, the jackets are pumped down to \(\sim 1 \times 10^{-5}\) Pa to remove as much air and other “contaminants” (if present) as possible before the cryogenic liquids are added. The helium jacket is generally precooled with liquid nitrogen at this stage, with the liquid nitrogen being removed before the liquid helium is added. After the cool down, the magnet is charged with electric current by connecting it to a special power supply. For an actively shielded 600 MHz magnet, a 134-A current is slowly introduced into the magnet coil until the magnetic-field strength reaches 14.09 T. Following this procedure, the cryoshim coils are also given appropriate currents. The optimal set of currents is determined by observation of the line shape of a water sample. Generally, one should be able to achieve a line width of less than 0.5 ppm with a reasonable line shape using only the cryoshim system. Once the magnet field strength is reached and the cryoshim currents have been optimized, a set of heaters that has kept some parts of the wire nonsuperconducting to allow connection to the power supply is carefully turned off to produce a self-contained superconducting magnet with persistent currents. The final step is the complete removal of the power supply from the magnet. The magnet is not connected to any source of power during operation and will continue to be persistent almost indefinitely, as long as it is kept at temperatures low enough to maintain the wires in the superconducting state.

Any coil produces a continuous field, both inside the coil and outside. The components of the field outside the coil affect the space around the magnet and could potentially present safety hazards for those working around the magnet. Magnets produced most recently are actively shielded. In actively shielded magnets, the field components outside the magnet housing are compensated with additional coils and special windings to minimize the intrusion of the magnetic field into that space. Active shielding allows much more effective use of laboratory space.

Magnets in the range of 300–500 MHz (proton frequency) are currently very popular in the analytical NMR laboratory. The use of magnets in the range of 600–750 MHz is becoming increasingly accessible as the technology becomes more stable and the costs of these
systems decrease. As of 2007, a 950 MHz magnet has been successfully tested in a manufacturing facility and will be relocated to a customer’s laboratory. Thus, one should expect the trend toward the use of ever-higher magnetic fields to continue for some time.

As we have mentioned, magnets are generally (if somewhat colloquially) specified by the proton resonance frequency and the diameter of the room-temperature bore. Thus, a 500/ SB MHz magnet means that the proton resonance frequency is 500 MHz and the room-temperature bore diameter is 54 mm (“standard bore”). There are also wide-bore (WB) systems, and these are similarly expressed as 500/WB, typically meaning a bore of 89 mm.

To maintain the magnet in the superconducting state, a weekly refill of the liquid nitrogen reservoir and a periodic refilling of the liquid helium reservoir (approximately every 2–5 months, depending on the magnet design) are required.

### 4.2 Signal Generation and Radio-frequency Amplifiers

In a modern NMR spectrometer, a set of RF transmitters produces the voltage that creates the perturbing time-dependent magnetic field. Usually, an RF transmitter consists of an RF source, a phase modulator, and an amplifier to generate the voltage of the desired amplitude, frequency, and phase. The phase modulator determines the phases of the pulses during the experiment, such that one may demand an \( x \), a \( y \), or any other pulse of RF magnetic field. The amplifier provides the RF voltage that impinges on the coil. It must be capable of providing outputs of a few watts (for a solution-state NMR spectrometer) to a few hundreds of watts or even kilowatts (for a solid-state NMR spectrometer).

The RF system provides the means to produce the voltages that excite the nuclei in the sample. The RF waveforms are generally produced at low power with various gating devices that allow the passage of RF current when an appropriate voltage is applied. The RF signal from a digital synthesizer passes through this stage, and from the output comes the appropriately modulated RF signal. The modulators in this stage are all connected to the AC that controls timing, frequency, shapes, phase, and amplitudes of the RF pulses according to the pulse program loaded into it from the primary computer. In modern NMR experiments, there are often excitations at several different frequencies for the various nuclei in a sample, so there are several channels, each similar to the others in function but working at a different frequency. When multiple RF channels are involved, all channels must be able to operate independently, as well as being synchronized with each other through their control by the AC. In a modern NMR spectrometer, the timing controllers are able to control more than 60 events with a timing resolution of 12 ns. The modulated output drives the high-power amplifiers that produce voltages corresponding to radiation up to several kilowatts across the sample coil.

All NMR experiments start from the operator’s instructions, a computer-programmed pulse sequence. In a pulse program, the frequencies, timing, phase, and amplitude of pulses in the channels are specified by the experimenter. This is usually done at the primary computer. Execution of the pulse program presents a series of digital instructions to the NMR spectrometer interface (usually through the intermediacy of the AC), containing a DAC that produces the appropriate analog waveform from the digital instructions of the pulse program. All “run-time” decisions, such as conditional loops and phase and frequency shifts, are made by the AC to control counters, gates, and electronic phase shifters in the RF signal-generation unit. The signal-generation unit creates the analog RF pulses and delays that drive the sample to make a response. A typical signal-generation unit has a frequency range of 3–1100 MHz, a frequency resolution less than 0.005 Hz, a switching time less than 300 ns, and phase resolution less than 0.006°. An additional function of a signal-generation unit is to produce reference signals, gating, and the dwell clock for the receivers.

The output of the signal-generation unit is passed to high-power RF amplifiers for further amplification. The output of the amplifiers is passed directly to the sample coil, where it perturbs the sample in a manner determined by the pulse program written by the experimenter. The high-power amplifier has a wide linear range (120 dB or more) so that it can accurately reproduce the RF signal passed to it. The RF output of the amplifier ranges from a few hundred watts for a solution-state spectrometer to a kilowatt for a solid-state spectrometer.

The pulse has a limited region of frequencies around the carrier frequency that it affects. The bandwidth of the excitation by an RF pulse is determined by the RF field strength, \( B_1 \), which also determines the 90° pulse width. The relationship between pulse width and the RF field strength is straightforward:

\[
\frac{\gamma B_1}{2\pi} = \frac{1}{PW_{360}} = \frac{1}{4PW_{90}} \text{ Hz}
\]

(3)

where \( PW_{360} \) and \( PW_{90} \) are the pulse widths for 360° and 90°, respectively. For example, a 90° pulse width of 10 μs corresponds to a \( B_1 \) field strength of 25 kHz, a typical value for pulse excitation on a modern solution NMR spectrometer. This pulse width is generally acceptable to excite the full range of possible nuclear frequencies for nuclei such as \(^1\text{H}\) and \(^{13}\text{C}\). This type of pulse is sometimes
Low power rectangular pulse

Shaped pulse

Figure 5  Schematic excitation profiles of a low-power rectangular pulse and a shaped pulse.

called a hard pulse. For some nuclei, a uniform excitation is not always possible using the conventional solution NMR hardware because of the large range of frequencies the excitation must span. As mentioned above, pulses also have phase properties that determine along which transverse axis, \( x, y, -x, \) or \(-y\), the magnetization lies after the RF pulse. This pulse phase is defined relative to an internal reference signal shared with all transmitter channels and receivers.

Pulse shapes also affect the excitation bandwidth. The common hard pulse described above is rectangular, with a finite width, constant amplitude, and phase. Sometimes it is necessary to excite a narrow region of the spectrum for selective transfer experiments, solvent suppression, and reduction of the dimensionality of multiple-dimension pulse sequences. In principle, the simple selective pulse can be a long, weak rectangular pulse. However, as shown in Figure 5, the excitation profile of a rectangular pulse often involves extended side lobes in the frequency excitation profile, which often create a sinc-like oscillation in the resulting spectrum. In principle, the simple selective pulse can be a long, weak rectangular pulse. However, as shown in Figure 5, the selective pulse, sometimes called a soft pulse, is mostly a shaped pulse, which is often used to smooth out the side lobes in the excitation profile caused by the rectangular pulse shape. The most commonly used shaped pulses have a profile of a ramp, a sine, a trapezoid, or a Gaussian. The selective shaped pulses, characterized by their duration, frequency profile, and phase behavior, are typically 1–100 ms in length, three orders of magnitude longer than the hard pulses.

4.3 Detection and Radio-frequency Receiver

Each RF channel is equipped with high-performance preamplifiers and RF receivers to detect and amplify the signal. Subsequent to excitation, the detected sample response is an analog voltage across the coil. The signal is ultimately converted to a digital form by a highly sophisticated ADC. The weak NMR signal (approximately microvolts) goes through preamplification while it is still a radio-frequency signal. This preamplification occurs in a unit separated from the console and located near the magnet to avoid loss in transmission through the cable. With an actively shielded magnet, the spectrometer console can be located much closer to the magnet than with a conventional magnet. In this case, the preamplifiers may be housed inside the spectrometer console to maximize the usage of laboratory space. The preamplified signal is usually then transformed into a lower-frequency signal by demodulation against a reference signal. After that, the lower-frequency signal is amplified again (often to filter high-frequency noise) to the level of several volts and finally digitized for storage and further processing.

A receiver must be able to amplify the signal over all frequencies within the spectral width (SW) linearly; otherwise, the amplitudes in the spectra cannot be used for quantitative results. In addition, the receiver must retain all phase information of the input signal. A large dynamic range is desirable for a receiver so that small signals in the spectrum are detected with appropriate ratios so that they can be quantitated. The receivers in modern spectrometers have variable gain under the control of the experimenter. It is very important to set the receiver gain properly. If the signal is overamplified (i.e. the gain is set very high so that receiver output is greater than 5 V), the digitizer is saturated by the largest signals, resulting in some signals seeming to have the same amplitude. A “clipped” FID is the result of saturating the digitizer. If the gain is too small, only a part of the dynamic range of a digitizer is used and poor reproduction of the signal results.

The chemical shift ranges (kilohertz) are much smaller than Larmor frequencies (typically tens or hundreds of megahertz). For example, the frequency range of a proton spectrum at 600 MHz is between 7 and 8 kHz, and is about 20 kHz for a \(^{13}\text{C}\) spectrum obtained on the same spectrometer. Often, one is only interested in chemical shift differences, instead of the absolute Larmor frequency. Therefore, it is a common approach to demodulate the signal to a lower frequency, which is equivalent to subtracting a reference frequency from the detected signal frequency before digitization. The reference frequency signal is usually chosen to be the carrier frequency of the exciting pulse. In addition, the RF signal is frequently referenced against a waveform with a phase reference differing by 90°. This gives the so-called in-phase and out-of-phase components of the signal, which are simultaneously digitized and stored together. This data detection protocol, referred to as quadrature
NUCLEAR MAGNETIC RESONANCE INSTRUMENTATION

detection, is widely used. It has the advantage that the
Fourier transform of the quadrature signal distinguishes
between positive and negative frequencies (relative to the
reference).

The digitizer works on the “sample and hold” principle,
in which the signal is sampled repetitively with a
specified interval. The time between samples is called the
dwell time ($DW$). The minimum DW one may use is
dictated by the Nyquist theorem, which states that the
digitization rate must be at least twice as large as the
highest frequency one wishes to observe. If the Nyquist
theorem is violated during digitization, spectral aliasing or
folding may occur, in which peaks that have frequencies
outside of the spectral window are detected as peaks
at frequencies within the spectral window, often with
a weaker intensity or a phase shift. To improve the
performance of digitization, one may use an analog or
digital filter to remove signals at frequencies outside of
the spectral window. Digital filtering has replaced analog
filtering done with passive analog electronic circuits.
Employing oversampling, where more points than
required by the Nyquist theorem are collected, has helped
the performance of digital filter programs and is common
in most modern spectrometers.

In quadrature detection, the NMR signal consists of
two time series related by the phase between the two
reference signals. Because there are twice as many data
in a quadrature set, the S/N in a spectrum collected
in the quadrature mode is increased by a factor of $\sqrt{2}$
over that of a spectrum that comes from a single time
series. In an experiment using quadrature detection, the
RF-pulse frequency is at the center of the spectrum to
assure a uniform excitation across the spectrum. Since
it is almost impossible to make the two channels in
the quadrature detection exactly identical, there are
sometimes quadrature-detection-related artifacts that
appear in the Fourier spectrum. Phase cycling of the
RF excitation and the detection in a repeated experiment
is often required to eliminate such artifacts.

4.4 The Spectrometer Field-frequency Lock System

The magnetic field and the frequency must both remain
constant to within at least one part in $10^{10}$ during
the course of an NMR experiment. Some experiments
such as $^{13}$C acquisition, 2-D, and 3-D experiments may
take several hours to several days. Magnetic fields of a
superconducting magnet drift more than this (one part
in $10^{10}$) over a period of time, which leads to a loss
of resolution in the NMR spectrum. To overcome the
field drift, a field-frequency lock system is widely used
in modern solution NMR spectrometers. The frequency
of the deuterium ($^2$H) signal of the deuterated solvent
of the sample is constantly monitored and reports on
the magnetic-field drift. The value of the deuterium
frequency is then used to “correct” for the field drift
by applying a small additional field parallel to the main
field using an RTS coil. This feedback system, which can
be considered a parallel spectrometer, is often referred to
as the lock channel. The lock channel contains a dedicated
transmitter, receiver, and compensation circuit.

The choice of the $^2$H signal to be that of the deuterated
solvent ($D_2O$, $CDCl_3$, $CD_3CN$, DMSO, etc.) is convenient
since the material is present in the sample and does not
genерally interfere with the spectroscopy of the commonly
observed nuclei. If the nucleus of detection is $^2$H, then one
usually uses the NMR spectrum of some other nucleus
(such as $^{19}$F or $^1$H) as the basis for the field-frequency
lock system.

The lock system works in the following way. The
absorption component of the $^2$H NMR signal of
the deuterated solvent is generally displayed by the
computer. The dispersion component is used to form
the compensation voltage that regulates the field, as
shown in Figure 6. When the magnetic-field shifts, there
is a change in the deuterium resonance frequency. The
error signal that occurs depends on the magnitude of the
frequency shift and on the direction of drift. This error
signal controls a feedback circuit that adjusts the current
in the $B_0$ shim coil in the RTS assembly to compensate for
the field drift. In most cases, the deuterium NMR signal is
detected by the CW method, because the CW method is
simple and provides sufficient sensitivity for monitoring
the frequency change of a single and strong resonance.

Since the lock channel is virtually a separate $^2$H NMR
spectrometer, its operation relies on careful settings of
the $^2$H transmitter power, the $^2$H receiver gain, and
the receiver phase. The highest possible lock transmitter

![Figure 6 The sign and magnitude of error signal from deuterated solvent is used in a frequency-lock feedback circuit to compensate the field drift.](image-url)
power (without saturation) ensures the highest sensitivity in the lock signal. Saturation of the $^2$H through use of too high a RF power will limit the ability to detect a frequency change. The amplifier gain controls the magnitude of the lock signal. If the gain is too low, the error signal is low and the amount of signal is not sufficient. On the other hand, excessively high amplification introduces unnecessary noise that may cause the lock to suffer random jumps. The error signal also depends on the proper setting of the lock phase.

### 4.5 The Shim System

The typical solution-station NMR resonance line widths in solution range from a few tenths of hertz to a few hertz. To maintain a magnetic field over an active volume of about 0.3–0.7 cm$^3$ and over a period of hours is extremely demanding. For example, in order to resolve fine structure with a splitting of the order of 0.5 Hz in a 600 MHz spectrometer, a relative field homogeneity $\Delta B/B_0$ of better than $10^{-9}$ is required. Inhomogeneous magnetic fields across the sample volume cause various distortions of the line shape, which leads to poor resolution and loss of sensitivity. Besides the careful design and construction of the superconducting solenoid, the magnetic field’s homogeneity is achieved by adjusting currents by two methods: cryoshimming and room-temperature shimming. The shim coils are a set of coils wound in various configurations that carry electric currents to generate small magnetic-field gradients to compensate or cancel out small gradients in the magnetic field of the large solenoid. The cryoshims are superconducting coils that are adjusted when the magnet is energized. The cryoshims remove gross inhomogeneities in the magnetic field.

It is important to remember at this juncture that the static field of the typical superconducting magnet and cryoshim system is already extremely homogeneous, often with inhomogeneities of no more than $10^{-8}$ over the volume of the sample. That high quality notwithstanding, to obtain the maximum performance required for high-resolution NMR, further optimization of the field homogeneity is needed. This second procedure is carried out with the RTS system. The set of room-temperature coils is mounted in the magnet bore surrounding the sample probe. The current in these coils is adjusted for each sample to compensate any remaining field gradients, specifically including gradients caused by differences from sample to sample.

The process of preparing the system to measure an NMR spectrum requires one to carry out what is called shimming, adjustment of the currents through the RTS coils to optimize the magnetic-field homogeneity across the sample volume, which allows one to maximize the sensitivity and resolution. Some people enjoy this iterative process, and some people find it an uncomfortable part of the setup to carry out the NMR experiment; it must be done with care to achieve a good NMR spectrum. To monitor homogeneity improvement while shimming, one uses the increase in the deuterium lock signal, or perhaps the time extent of an FID, to indicate approach to the optimal conditions. In addition, one sometimes examines the line shape of some resonance to ensure a combination of narrowness of the resonance band with a symmetric line shape. As discussed below, modern instruments are often equipped with triple-axis pulse field gradients, and shimming can be performed automatically by first mapping the magnetic-filed profile in the sample and then compensating for the field inhomogeneity with adjustments of the appropriate RTS coils.

There are two types of shim coils, axial and transverse, which are also known as spinning and nonspinning shims, respectively, to indicate the condition under which each is adjusted. Each shim coil is designed to produce a gradient profile near the center of the coil that varies as a specific mathematical function of the coordinates. The basis set functions corresponding to the individual coil geometries in almost all spectrometers are the spherical harmonic functions, the solutions of Laplace’s equation. The coils are therefore labeled by the Cartesian representation of the appropriate spherical harmonic function. Table 1 lists 17 of the RTSs and their corresponding labels. In some spectrometers, there may be as many as 64 RTSs that can be adjusted. The spinning shims have orientations that produce a gradient along the axis of sample rotation. They are best adjusted when the sample is spinning. The nonspinning shims are adjusted without sample rotation because they produce gradients perpendicular to the direction of the main field. Rotation would average these out, and one wishes to compensate them with the gradient coils, so the adjustment is done without spinning.

One of the most exciting developments in the NMR instrumentation in recent years is the gradient-shimming method, which completely changes the conventional method of magnet shimming described above. Gradient shimming utilizes a gradient-echo sequence. The result of this process is a resonance phase map, which directly correlates to the field inhomogeneity across the sample. This profile is obtained experimentally and is compared with a reference phase map previously recorded on the basis of the known electric current settings of each individual shim coil, so that all required changes of current in each shim coil can be calculated. The gradient-shimming method was first applied to NMR spectroscopy of biomolecular samples that had a strong solvent (90% H$_2$O) signal. The strong solvent signal is used to map the inhomogeneity across the active sample volume in three dimensions. The gradient-shimming method is now
available for samples in organic solvents where the $^2$H resonance of a deuterated solvent is observed through the lock channel for inhomogeneity mapping. The accessory required for $^2$H gradient shimming is now a standard part of a commercial spectrometer. An example of gradient shimming is shown in Figure 7, where spectrum A is taken with the current in all RTSs set to zero and spectrum B is obtained after a two-minute $^2$H gradient shimming with only one iteration. The high efficiency of shimming demonstrated here is almost impossible to achieve by the manual iterative technique, even for experienced NMR spectroscists.

## 4.6 The Pulsed-field-gradient Amplifier

The use of the PFG method has become very popular because of its applications in a wide variety of experiments, including coherence selection, solvent suppression, gradient shimming, and its use as a spoil pulse to dephase magnetization. The technique works by transiently applying a magnetic-field gradient to the sample through a gradient coil in the probe, along the $z$ axis (single-axis gradient) or along $x, y,$ and $z$ axes (three-axis gradients). The gradient amplifier is operated independently from, but is always in synchrony with, the RF channels. Usually a gradient-control unit generates the gradient pulse on the basis of commands from the pulse program. Since the gradient pulse involves application of a high direct current across the gradient coil, residual eddy currents are unavoidable. Most commercial systems have self-screening to minimize the influence of these eddy currents. The shape of the gradient can be linear or rectangular, but other shapes can be programmed as well. For reduction of eddy currents, the gradient pulse shape may be a sinusoidal waveform. Like an RF pulse, a gradient pulse is specified by duration, a shape, an amplitude, and a polarity.

## 4.7 The Computer and Software

There are at least two computers and a number of microprocessors in a spectrometer. The primary computer provides the GUI to the spectroscopist. The computer controls spectrometer action, processes and displays, and data, and performs other tasks necessary to obtain a spectrum. The primary computer usually is a Linux workstation running Enterprise WS4 or WS5, or a PC running Windows Vista or XP. A typical workstation configuration includes 1 GB of internal memory, a 200 GB hard drive, and a 19” (or larger) flat panel monitor, a DVD/CD-R drive, and two network cards for spectrometer and local area network (LAN) connections. With rapid developments in computer information technology, the specific characteristics of the primary computer change almost on a monthly basis. Using the GUI of the primary computer, the NMR spectroscopist selects an experiment from a list of experimental protocols, changes the parameters if necessary, and commands the computer to start the experiment. The spectroscopist's instructions are sent from the primary computer to an AC located in the console through an Ethernet connection. The AC works as an interface between the transmitter, receiver, lock channel, gradient amplifier, probe, and the primary computer. This computer does not perform onboard data manipulation and only transmits data between various spectrometer components. The communication to timing-critical units such as receiver, transmitter, digitizer, and lock channel is carried out through a high-speed virtual memory expansion (VME) data bus. The Ethernet link

Figure 7 The gradient-shimming method: $^1$H spectrum of gramicidine-S in DMSO-d$_6$. The bottom trace (a) was obtained by setting all on-axis shims to zero. After a deuterated gradient shimming of z1–z5 for a few minutes, a high-resolution spectrum (b) was obtained.

to the primary computer provides an effective connection by which the commands entered at the operator’s desk are transmitted to the AC and hence to various spectrometer components. Non-timing-critical units such as the variable temperature control, the pneumatic unit for probe control, and the automatic sample changer are connected to the spectrometer computer through an RS-232 or RS-485 bus.

Acquired and digitized data are transferred to the primary computer for storage and further processing. Data are saved on a hard drive and may be transferred to a file server through an Ethernet connection. The time-domain data are generally transformed into a frequency-domain spectrum by NMR software resident in the primary computer. A local printer or a network printer can be used to plot the spectrum obtained through this process.

NMR software has several major functions: spectrometer control, data acquisition, and data processing. Most NMR software code is written in the C and C++ programming languages, but may include recent Java and Tcl/Tk add-ons on a Linux- or a Windows-based PC computer. The software packages have an extensive microprogramming language for operators to develop automated operations, to control the spectrometer, and to process the data. The NMR software package is usually accessed through the graphical interface. NMR software usually presents a large display of the current NMR data in either the time or the frequency domain. The program subroutines can be accessed through drop-down menus with many levels of commands that handle tasks from data acquisition to processing. Most commands can also be entered through a command line. There are also control icons for quick access to many routinely used procedures. Interactive operations, such as spectral display, phasing, peak picking, and integration are done by convenient mouse operations.

Automation of operations is an important convenient feature of recently released NMR software. This is especially useful for laboratories where minimally trained users submit samples. The user places the NMR sample on a sample changer carousel and selects the NMR experiments to be carried out through the GUI of the spectrometer’s primary computer. The sample is automatically moved, at the appropriate time, from the carousel to the NMR probe by the sample changer, and
the experiment preparation and execution are carried out by the NMR software with basically no intervention from the user. After data acquisition and reduction, a notification of the experiment, usually including the processed NMR spectrum as a portable document format (PDF) file, is sent to the user through an email. The system administrator may choose to archive acquired data to a network data server through a network file system (NFS) protocol or other Internet file-transfer protocols.

A database is used to manage all pulses and other experimental parameters, including durations and power levels for RF pulses for each probe. These parameters can be easily accessed when a new experimental protocol is to be parameterized. As a part of the software package, there are many modules to perform specific functions, such as nuclear relaxation analysis, analysis of shaped pulses, spectral simulation, and experimental simulation, as well as graphic display of the pulse program. A molecular drawing program is even included in some NMR packages for users to document molecular structures for each spectrum. Recently released software also provides web access, which allows users to check the status of data acquisition and to control the spectrometer through the Internet. In addition, there are frequently subroutines for calculation of theoretical spectra or fitting the spectra to some form. NMR software continues to be a fast-developing component of most modern NMR spectrometers, a result of the rapid advances in computer technology and programming.

4.8 The Nuclear Magnetic Resonance Probe

The NMR probe, housing the sample for analysis, transmits RF radiation to the sample and detects the weak NMR response. Most solution NMR probes are mounted in the magnet bore from the bottom of the magnet. For insertion of the sample, a spinner loaded with the NMR sample tube is placed into the probe from the top of the magnet bore. A pneumatic device supplies a cushion of air or nitrogen gas that buoys the spinner/sample combination, allows it to be slowly positioned into the probe as the pressure is reduced, and finally ejects the spinner when the experiment is finished. The sample tube, surrounded by the RF coils, is usually spun at 15–20 Hz to reduce residual magnetic-field inhomogeneities. A simplified schematic diagram of the NMR probe and sample spinner is given in Figure 8.

In general, the sample temperature in the NMR probe can be controlled from −100 to +150 °C to within ±0.1 °C. If the desired sample temperature is higher than room temperature, heated air or nitrogen gas is passed over the sample tube. Cold nitrogen gas generated by a heater immersed in a liquid nitrogen dewar is used as a thermally controlled bath for the sample if the desired sample temperature is below room temperature. Recently, various gas refrigeration devices have become available commercially for cooling nitrogen gas before it is introduced into the probe for temperature regulation at or slightly below room temperature.

A simplified probe (LC) circuit, which consists of an RF coil having inductance L and two variable capacitors, is given in Figure 9. Optimal performance of the NMR spectrometer depends critically on detection sensitivity, which is achieved by adjusting the tuning capacitor $C_T$ and matching capacitor $C_M$ such that the resonance frequency of the probe LC circuit is the nuclear Larmor frequency and the impedance of the circuit is matched to 50 Ω.
In general, insertion of a sample changes the tuning of the probe circuit. Samples containing a high-dielectric material (such as water) may particularly cause a change in probe tuning. Samples that are electrically conducting cause significant changes in both matching and tuning. Therefore, it is imperative to tune and match the probe for each sample. As shown in Figure 8, conventional probe tuning and matching knobs that control the capacitor settings are located at the bottom of the probe. To tune the probe circuit at the appropriate frequency, the response of an RF channel to an imposed RF voltage is compared to the response of a purely resistive 50 Ω load. The RF voltage is generally swept through a range of frequencies as it originates from a sweep generator. Adjustment of the two capacitors, usually by iterative changes, produces a situation in which the RF response of the circuit appears identical to that of the purely resistive load. To aid in this tuning step, the reflected voltage from the circuit is usually displayed through a GUI at the primary computer display. Sometimes, the response is sent to an array of light-emitting diodes (LED), which report the reflected voltage as a string of lit diodes. Whatever the device for detection, the object of the tuning step is to minimize reflected RF voltage from the probe RF circuit.

Tuning the probe circuit requires a set of skills of the user. It can be a time-consuming and frustrating process for one who has not experienced the process. A recent development in the NMR probe technology is ATM by a device that carries out this procedure automatically under software control. The advantage of ATM is especially obvious in an open-access NMR laboratory, where many users are untrained or minimally trained in tuning RF circuits.

Various high-resolution probes for study of solution-state samples are commercially available. Each type of probe meets some requirements for specific applications in chemistry, biochemistry, and material sciences. However, many features are common to all probes, which makes it possible to classify probes into well-defined groups according to the particular values of certain parameters. For example, commercial probes are determined by the sample tube diameter. Currently, one may purchase probes that accept tubes with diameters of 1.7, 2.5, 5, 8, 10, and 20 mm. The choice of diameter depends on the application. Probes with a diameter of less than 3 mm are called microsample probes and are used in situations where the amount of sample is limited. The high efficiency of a microsample probe is a result of a high filling factor due to the limited volume of the sample tube. The most commonly used NMR probes accept 5-mm-diameter NMR tubes. Probes for larger tubes can be employed for special applications, where the sensitivity of the measurement is limited.

Besides the sample tube diameter, solution NMR probes can be classified as standard or inverse based on the configuration for signal detection and for decoupling. A typical standard high-resolution probe has at least two RF coils. The inner coil is for the X-nucleus detection, while the outer coil is mainly used for 1H decoupling. The outer coil is sometimes used for observation of a nuclear signal as well, but this almost always involves a lower sensitivity. The outer (or 1H) coil is usually doubly tuned to allow it to be used to detect the 2H resonance for use in the field-frequency lock system. In some probes, the X channel is tuned only at a fixed frequency (e.g. 13C). However, there are so-called broadband probes in which the frequency may be tuned over a range to allow detection of a variety of nuclei. A typical configuration for a broadband probe might allow detection of nuclei that have frequencies in the range from 109Ag to 31P. The standard probe is generally optimized to observe an X nucleus, normally 13C, while allowing decoupling of protons. Other standard probes may be tuned for multiple resonances in the X channel, for example by throwing a switch. One such probe is the so-called quad nuclei probe that has an inner coil tuned to predefined nuclei, usually 31P, 13C, and 15N, or 19F, 31P, and 13C. In such probes, the outer coil is doubly tuned to 1H and 2H.

An inverse probe reverses the uses of the inner and outer coils. The inner coil is tuned to the 1H resonance frequency and the outer coil is used for the X-nucleus frequency (13C, 15N, 31P, etc.). Such probes are often used when one wishes to detect the 1H resonance while applying decoupling power to the X nucleus. Because of the high sensitivity of 1H detection, inverse probes have been widely used for indirect-detection 2-D experiments such as heteronuclear multiple quantum correlation (HMQC) and heteronuclear multiple band correlation (HMBC). Inverse probes are also optimized for 2-D 1H–1H correlation experiments such as the correlated spectroscopy (COSY) experiment and the nuclear Overhauser effect spectroscopy (NOESY) experiment. Most triple-resonance probes (that can be used for detection or decoupling of three different nuclei in an experiment) are of the inverse design, with an inner coil...
tuned to $^1$H resonance frequency and an outer coil doubly tuned for simultaneous decoupling two nuclei, often $^{13}$C and $^{15}$N.

Another aspect of probe technology is the incorporation of coils that allow the generation of PFGs. For most of multiple-dimensional experiments it is necessary to apply a gradient to the main field for a short time, which is accommodated by these coils. The gradient coils are actively shielded, with stray magnetic fields screened by a second coil located around the principal gradient coil. Some probes contain a single $z$-gradient coil that provides a linear gradient in the direction of the main magnetic field. For more complex experiments, one may also purchase probes that contain an assembly of gradient coils that independently generate linear gradients in each of the three orthogonal directions $x$, $y$, and $z$ to allow a succession of different gradients that are required in some sophisticated experiments.

For special experimental situations such as LC-NMR, the probe has to be designed to accommodate the needs of the other procedure. In particular, in LC-NMR the sample flows through a capillary tube, the active volume of which is only microliters. The inverse mode is often used for LC probe to provide enhanced sensitivity for $^1$H observation. Inverse operation is necessitated because of the small amount of sample. Another kind of probe used widely in industrial laboratories is a high-throughput flow probe, similar in concept to the probe used in LC-NMR. In these probes, a capillary tube is used as a sample tube with a volume of a few hundred microliters.

One of the most exiting developments in probe technology in recent years is the cryogenically cooled probe. Such a probe was proposed decades ago but it has only recently become commercially available. The cryogenically cooled probe offers a dramatic increase in the S/N by reducing the operating temperature of the NMR coil assembly and preamplifiers to 25–30 and 77 K, respectively, which reduces the inherent noise in the RF circuits. The probe coils, a few millimeters away from the sample tube, which is usually near room temperature, are cooled with cold helium gas that is controlled by an automatic closed-cycle cooling system. The cryogenically cooled probe can be configured as a standard probe where the inner coil is for X detection or as an inverse probe. In the standard configuration, the cooled probe can be used for collecting natural-abundance $^{15}$N spectra and even for acquiring $^{23}$C spectra of high-molecular-weight polymers where the sample is maintained at high temperature. The ability to insulate the region of the RF coils from a very different temperature at the sample (which is only millimeters away) is one of the triumphs of the design of NMR technology. Triple-resonance cryogenic probes operated in the inverse mode have been extensively used for analysis of proteins, as well as for other biomolecular analyses. It appears that, the high cost and demanding requirements for laboratory infrastructure notwithstanding, cryogenically cooled probes are becoming mainstays of industrial, academic, and government NMR laboratories.

4.9 Automation and Sample Changers

In the modern NMR laboratory, more and more work is performed automatically. While all of the operations of the spectroscopy have been under computer control for many years, it is only recently that the initial step of selecting and inserting a sample has become a fully automated part of the process of acquiring an NMR spectrum. The sample changer is, at its heart, a robot that selects a specific sample by command of the computer and places it in the NMR spectrometer; at the end of an acquisition, it reverses this process by ejecting the sample. The choice of a particular sample changer depends on the number of samples to be analyzed. A small sample changer that can handle from 8 to 24 samples is typically mounted on top of the magnet and samples are analyzed sequentially. A larger sample changer (handling up to 120 samples) is often floor-mounted and uses pneumatic or magnet-mounted arms to move the sample between the magnet and sample carousel. NMR software controls the queuing system and determines when a sample is analyzed on the basis of queueing rules preprogrammed by the system administrator.

5 PRACTICAL ASPECTS OF NUCLEAR MAGNETIC RESONANCE SPECTROMETER OPERATION

To obtain a high-quality spectrum, the sample must be prepared carefully. The appropriate NMR probe and experiments must be chosen for the specific application. The standard experimental procedures must be followed to assure reproducibility and accuracy of measurements. As with any experimental procedure, safety precautions must be observed. In this section, practical details of procedures and precautions are discussed.

5.1 Safety Precautions

Extreme caution must be taken while working around magnets, particularly when magnetic materials such as gas cylinders and tools are used in the vicinity of the magnets. Persons with medical metal implants must consult a physician before working around magnets. Credit cards and other magnetic recording materials must be kept away from the magnets.
5.2 Sample Preparation

Sample preparation is the first step, and a critical one, if one is to obtain a high-quality NMR spectrum. Usually the sample is dissolved in a deuterated solvent that serves at the same time as the origin of the lock signal. A list of common NMR solvents is given in Table 2, along with chemical shift references and other physical properties. Nonviscous solvents provide a sharp NMR resonance and are always the preferred choice for use in preparing a sample. If a solvent is viscous but necessary to the chemistry, NMR spectra may be acquired at an elevated temperature to increase the mobility of the solute and solvent molecules to improve the resolution. It is preferable to avoid the overlap of NMR signals from the residual protonated solvent molecule and the sample signal, if possible. If temperature is a variable in the NMR measurement, boiling point and melting point of the solvent must be taken into consideration. If a large amount of the solvent is to be used for NMR analysis, then cost may also be a factor in the solvent selection. Deuterated chloroform is, by far, the most widely used solvent for studies involving organic molecules. Deuterated acetone, because of its low viscosity and very sharp resonance, is often used as the standard sample for establishing homogeneity of the magnetic field. Because of its ability to dissolve many organic materials, deuterated dimethylsulfoxide (DMSO) has also become popular as a solvent for NMR studies. In studies of biological macromolecular systems, detection of amide and imido protons is critical to structure determination with NMR. A mixture of 90% H₂O with 10% D₂O is often used as the solvent in these studies to limit deuterium exchange from D₂O to backbone amide NH protons in peptides and proteins or to imido protons of DNA and RNA base pairs. Because H₂O gives a large signal in the proton spectrum of these solutions, solvent-suppression techniques to reduce the intensity of the water signal have been developed.

For obtaining a ¹H NMR spectrum, the sample concentration should be kept at moderate or low levels to reduce spectral artifacts, such as spinning sidebands. For a ¹³C analysis in which the natural abundance limits the signal strength, a high sample concentration is preferable.

There are several features of solution preparation that are necessary to ensure a high-quality spectrum. Insoluble particles suspended in the solution to be analyzed lead to a situation in which the NMR resonances are often poorly resolved. Generally, careful filtration of the solution is recommended. Gases, especially oxygen, dissolved in the solution provide additional nuclear spin relaxation pathways for the spins in the analyte, with the net effect that the resonances may be broader than one might expect. The result is that the resonances are less well resolved. Degassing the sample by the freeze-pump-thaw method can generally reduce the amount of dissolved gas in a sample. It is especially important to carry out this removal of dissolved oxygen if the experiment involves measuring the intrinsic relaxation rate for the analyte. As an internal standard of the chemical shift, a trace amount of tetramethylsilane (TMS, 0.0 ppm) is added to a sample as an internal chemical shift reference. Sometimes, the residual proton signal of a deuterated solvent may also be used as a secondary chemical shift reference, rather than adding TMS. The $^1$H and $^{13}$C chemical shifts with respect to TMS of some common NMR solvent are listed in Table 2.

### 5.3 Data Acquisition

After a sample is loaded into a probe, acquisition parameters, including observe and decoupling frequencies, are loaded into the data directory of the current experiment by a command to the NMR-control software. If the sample is to be examined at a temperature other than room temperature, the temperature controller is adjusted and a sufficient time for temperature equilibration must be allowed. It is important to note that the temperature that is reported by the hardware is not the temperature at the sample, and the temperature must be determined by some previous calibration of the system.

The probe must be tuned to the frequencies specified by the acquisition parameters. In addition to sample properties, temperature is a variable that may affect the tuning, so it is important to allow the probe to equilibrate before carrying out tuning. The tuning and matching capacitors of the probe LC circuit are adjusted iteratively until the circuit is resonant at the appropriate frequency and its impedance is matched to that of the spectrometer’s RF output.

To average out inhomogeneities across the active volume, the sample is spun at 15–20 Hz. To begin, the $^2$H signal of the deuterated NMR solvent is located by adjusting magnetic-field offset while keeping the deuterium frequency constant. Once the lock signal is found, the magnetic field is locked with the solvent deuterium signal on resonance. After the frequency lock has been established, the magnetic-field homogeneity in the active sample volume is optimized by shimming. Shimming is carried out iteratively. The procedure begins by adjusting the spinning shims iteratively until no improvement in the lock level is possible. The sample spinning is stopped, and the nonspinning shims are adjusted iteratively until the optimal condition is achieved. Although these two steps sound straightforward, the iteration among a large number of shims takes some time, unless performed automatically. With proper room-temperature shimming, the $^1$H line width of typical small organic molecules such as CHCl$_3$ can be improved from a few hundred hertz in a cryoshimmed magnet to a few tenths of a hertz. For a routine operation in a properly maintained spectrometer, shimming generally only involves adjusting the first- and/or the second-order shims when the sample is changed. However, for a new probe or spectrometer, shimming to a proper line resolution and line shape may take hours or even days.

Before beginning the acquisition of data, one must choose the appropriate pulse program and enter the appropriate acquisition parameters, including pulse widths, related power levels, SW, number of data points to be acquired (time domain, TD), DW, and number of scans (NS) to be coadded. In some cases, one may obtain the appropriate set of acquisition parameters from files saved on the computer, particularly for routine $^1$H and $^{13}$C experiments. Calibration of pulse widths and amplitudes must be done routinely and properly documented.

Here we discuss some of the parameters that must be adjusted before beginning an experiment with quadrature detection. In quadrature detection, the transmitter frequency should be placed at the center of the SW such that only a frequency range of ±SW/2 needs to be digitized. The data-sampling rate, dictated by the Nyquist criterion, must be larger than or equal to SW (i.e. 2 × (SW/2)). By this requirement, the relation of the sweep width to the data-sampling time interval, or DW, is as follows:

$$DW = \frac{1}{SW}$$

(4)

The total acquisition time (AT) is simply the product of the dwell time and half of the time-domain data points (TD/2), which provides the following relation:

$$AT = DW TD \frac{T D}{2} = \frac{1}{SW} TD \frac{T D}{2}$$

(5)

The digital resolution (DR) of the spectrum is defined as the ratio of total SW in hertz to the total number of points in the spectrum. If zero filling is not applied to the time-domain data set before FT, the number of points in the frequency-domain spectrum is one half of TD or
The DR can then be expressed as

\[ DR = \frac{SW}{(TD/2)} \frac{1}{AT} \]  

(6)

As shown in Equation (6), digital resolution is simply the reciprocal of the total acquisition time. DR should always be smaller than the natural line width of the NMR resonances of the sample to assure the ability to resolve fine structure. For a typical \(^1\text{H}\) spectrum, the resonance line width ranges from a few tenths of a hertz to a few hertz, and the AT must be set to a few seconds or longer. Prior to data acquisition, the receiver gain should be adjusted to prevent the signal from being too large or too small for the detection; it is particularly important that the gain be not so big as to produce signals that saturate the ADC converter, a situation that introduces artifacts into the spectrum. The acquisition is generally terminated when the number of FIDs requested by the operator have been added together, given the symbol NS or NA. Most NMR-control programs allow the spectrometer operator to terminate acquisition for any reason at any time before NS is reached.

### 5.4 Data Processing and Reduction

Upon the completion of data acquisition, the FID is generally apodized by multiplication with a function defined by the operator. This action is usually done to improve either the S/N or the resolution. To ensure that zero-frequency artifacts are minimized at this point, the average of the data over some region is subtracted from each point to ensure that the oscillation is about the zero of the data. After manipulation of the data by these procedures, the data are ready to analyze. The FFT is used to convert the time-domain FID to a frequency-domain spectrum. Subsequent to this procedure, the NMR spectrum may require a phase correction, which can be carried out with a subroutine. In addition, the spectrum may be further treated to “flatten the baseline”. Here a standard protocol is used to determine the low-frequency broad components of the spectrum, often by fitting certain parts of the spectrum and subtracting, in a point-by-point fashion, to “remove” these components from the spectrum.

An important part of presenting a spectrum is ensuring that the data are properly referenced. This referencing is frequently done by choosing the peak representative of a particular chemical shift (0.0 ppm for TMS) and issuing a command to the computer to set all frequencies relative to its frequency, the reference position. If the TMS signal is absent from the spectrum, one sometimes uses the residual \(^1\text{H}\) signals of the deuterated solvent as a secondary chemical shift reference.

At this point, one usually wishes to identify all of the resonances in the spectrum by specifying their positions relative to the reference. This can be done manually, but there are computer programs that can also perform this operation. In the semiautomatic mode, the spectrometer operator sets the minimum and maximum limits for the program to accept as a peak. The process of identifying the resonances in this manner is called peak picking. Most NMR software automatically labels the chemical shift of each peak found between the limits defined by user with its chemical shift.

An important quality is the relative amount of signal corresponding to each peak. This is found by integration of the peak. The spectrometer operator may use a software function to select spectral regions for automatic calculation of the peak integrals. These are displayed on the graphical presentation of the spectrum and are frequently listed in a table generated by the software.

At this point, the only remaining procedure is to make a hard-copy version of the spectrum. Most NMR software provides a plotting facility to do this. Depending on the needs of the spectroscopist, one may plot different regions of the spectrum to demonstrate some particularly important aspect of the data. The format of the plot depends on the kind of experiment. For multidimensional experiments, the plotting may be quite complicated. For example, for 2-D experiments, the “forest” style plot that was prevalent in early versions of NMR software has now been replaced almost completely by the contour plot.

The operating procedures discussed above are summarized in Figure 10. All steps can be automated in an

![Figure 10](attachment:image.png)
open-access NMR laboratory. It is worthwhile to mention that the automation procedures are suitable to a direct-injection autosampler system. Samples are extracted from vials or well plates with a needle that can be injected into a capillary tube. The capillary tube allows flow into the NMR-active region, where the sample is analyzed. The typical probe used in this flow injection autosampler system is an ATM capillary-flow probe.

6 FUTURE PERSPECTIVES IN THE DEVELOPMENT OF NUCLEAR MAGNETIC RESONANCE SPECTROMETERS

As the NMR spectrometer is one of the critical tools used in industrial, academic, and government laboratories, each development that improves the NMR spectrometer has made a significant impact on the chemical, pharmaceutical, and biotechnology industries. There is no doubt that this trend will continue. Newly introduced methods and techniques have been quickly applied to all areas of NMR instrumentation, whether they be developments affecting the magnet, the probe, the console, the computer hardware, or the NMR software. In general, the developments have focused on enhancement of sensitivity and resolution, automation of the spectrometer operation, reduction of space required for the NMR system, enhancing the reliability of components, mating NMR with other technologies to provide synergy, and ease of operation by less-experienced users.

The driving force to produce ever-higher magnetic field is the enhancement of sensitivity and resolution, especially for the analysis of biological macromolecular samples in solution or in solids. In the solid state, quadrupolar coupling, which broadens the NMR line of nuclei possessing a spin greater than 1/2 (two-thirds of the elements in the periodic table), can be made nearly first order in sufficient high fields. Thus, there is a tremendous emphasis in both solid- and solution-state NMR to provide reliable magnets with higher fields, such as the recently introduced 950 MHz spectrometer. This trend will not slow down in the future.

The introduction of actively shielded magnets has led to less need for laboratory space. For example, the 5-G line of an actively shielded Bruker BioSpin 800 MHz magnet is about 1.5 m, which is comparable to the stray field footprint of an unshielded 300 MHz magnet. This means a great reduction in the space required for NMR spectrometers. It is certain that there will be continual pressure to replace older magnets with modern shielded magnets.

The conservation of cryogenic liquids (nitrogen and helium) is another driving force in the development of magnet technology, particularly as these liquids become harder to obtain and therefore more expensive. Several commercial systems exist for this purpose. For example, using the excess cooling power of a cooling unit for a cryogenically cooled probe, nitrogen gas can be condensed and introduced back into the nitrogen chamber of the magnet for reuse. With this technique, it is possible to eliminates or reduce the number of liquid nitrogen refills, reduce cryogen costs, and increase the flexibility for performing long-term experiments by eliminating interruptions for nitrogen refills.

Considering that helium is a nonrenewable resource, it is anticipated, not too far in the future, that similar techniques will be employed to cool down helium gas from the boil-off to help maintain the temperature of the superconducting solenoid. Even now, it has become economically feasible and socially important to collect helium boil-off gas and return the gas, rather than allow it to escape into space.

A great potential saving may accrue if the new technologies in high-temperature superconducting materials can be used to replace the current superconducting materials that require cooling to liquid helium temperatures with materials that only require cooling to liquid nitrogen temperatures. There are still many technological hurdles to overcome before this becomes reality, and there might be some technological reasons that it cannot be done, but if such a magnet could be developed, it would have a tremendous impact on the way in which NMR spectroscopy is done.

With the rapid development of digital electronics, much of the spectrometer control and operation have been consolidated onto a single computer motherboard. For example, identical peripheral component interconnect (PCI) cards perform individual functionalities, such as timing, frequency, and gradient controlling, depending on a preloaded firmware. The communication backbone of the NMR spectrometer now consists of two data paths, a LAN-based approach (Ethernet) for non-time-critical operations (diagnostics, firmware upgrades, and configuration parameters) and an ultrafast low-voltage differential signaling (LVDS) bus for time-critical (real-time) applications (pulse timing, loop, and other real-time decisions). The resolutions of frequency and timing control have been greatly improved with LVDS communications. Special ADC architectures have been developed in which the dynamic range of the digitizer is expanded from the previous 16 to 22 bits. In addition, receiver bandwidth has been expanded to as much as 5 MHz. Both of these developments benefit areas such as polymer analysis, solid-state applications, and impurity detection in mixtures.
With wide-bandwidth receivers, a recent technique of parallel detection of multiple nuclei\(^1\) allows simultaneous recording of multiple-dimension NMR spectra for more than one nucleus. This method reduces the total time required for data collection per sample. A further development by Varian of a receiver with a single 80 MHz ADC to digitize the NMR signal directly at the intermediate frequency provides spectra quickly with fewer steps: these spectra have flat baselines and are free of quadrature detection–related artifacts. This new capability allows single-scan operation with the associated higher throughput when sensitivity is not an issue. It is anticipated that more and more ultrafast ADC will become available and be used in an NMR spectrometer.

To obtain information on the absolute concentration of individual components of a mixture with \(^1\)H NMR spectroscopy requires the addition of an external reference compound that may overlap some of the resonance of the material to be analyzed. A new technique\(^2\) employs an artificial electronically synthesized reference signal, which can be tuned in terms of chemical shift displacement and amplitude to suit the particular constraints of the experiments. This effectively replaces the external reference and avoids contaminating the sample.

The most active area in NMR instrumentation development in recent years has been probe development. In particular, cryogenically cooled probes have begun to be utilized in a wide variety of applications, not only in complex biological systems but also in small molecule structure elucidation in organic and inorganic chemistry. The principal advantage of a cryogenically cooled probe is the tremendous increase in S/N, which makes possible a substantial reduction in total time required for data collection, in some cases by up to a factor of 16 when compared with a conventional probe. The cryogenically cooled probes also allow the detection of \(^1\)H and \(^{13}\)C NMR spectra of extremely small (\(\sim 30 \mu\text{L}\)) samples often found in studies in drug research in the pharmaceutical industry. For the same reason, cryogenically cooled probes have a great potential in the NMR microimaging probes.

In solid-state NMR, similar probe developments have provided new arenas for experimentalists. The development of the ultrafast MAS probes that spin up to 70 kHz has been offered improved spectral resolutions for \(^1\)H and has eliminated the need of high-power decoupling. In biosolid NMR applications, RF heating in the sample chamber due to electric fields (E-fields) of the RF pulses severely affects the lifetime of the biosolid sample under MAS conditions.\(^3,4\) New coil designs from Bruker and Varian reduce or eliminate RF heating caused by the E-field.

NMR software packages have been continuously updated to be consistent with advances in hardware. Most NMR software is designed for operation under Windows and Linux operating systems. The software generally has a straightforward interface that takes advantage of widespread PC standards that are commonly used in word processing, graphics, and presentation programs. Recent versions of NMR software keep track of NMR experimental parameters for each probe by retrieving information stored in a microchip in the probe. With these new versions, the RF power is monitored under software control to ensure that power does not exceed the limit for each probe; if this happens, the software terminates the experiment to prevent damage to the probe.

Another innovation is web-based access to the spectrometer through a new generation of software. With this software, one may monitor the status of an experiment or even start and terminate an experiment from a remote computer. With further development of this sort of software control, an operator will soon be able to access and control the NMR spectrometer through a cellular phone or other mobile communication device. A recent software development is the integration of accounting programs into the software to track usage for administrative purposes.

The developments in software, from remote control to automation, have changed the concept of spectrometer operation. For example, the tedious work associated with magnetic-field shimming has been greatly reduced with the utilization the gradient-echo technique. Using a new algorithm available in the most recently released software by Bruker, it takes less than 1 h for a spectrometer operator to produce a homogeneous magnetic field that meets the resolution and line-shape requirements, started from a newly installed magnet. Without this spectrometer automation, the same process may have taken a few days for an experienced console engineer to accomplish when this was done manually.

One should expect that integrated analytical systems involving hyphenated techniques that involve NMR will continue to grow in importance. The combinations of LC with NMR and of LC-MS with NMR are now popular options for an analytical chemist. Integrated software that interprets NMR spectra and correlates the structural features from various analytical techniques is the next logical point for development as these hyphenated techniques become more common in the analytical laboratory.

Nuclear Magnetic Resonance of Geological Materials and Glasses

Grainne Moran and Russell F. Howe
University of New South Wales, Sydney, Australia

This article concerns the application of nuclear magnetic resonance (NMR) spectroscopic techniques to the analysis of geological materials and glasses. It includes inorganic minerals and glasses, but does not cover soils and clay minerals to any extent. The first part presents an overview of solid-state NMR experiments applicable to inorganic solids. The range of nuclei accessible by NMR and the particular requirements for obtaining good spectra of more difficult nuclei, including quadrupolar nuclei, are discussed. The experimental conditions under which solid-state NMR can provide quantitative analytical measurements are also considered.

NMR spectroscopy provides element-specific speciation and structural information including coordination environment and bond distances. It is particularly valuable for the analysis of amorphous and partially crystalline materials not amenable to structure determination by X-ray diffraction. NMR can detect and quantify materials containing multiple phases and can be used for in situ monitoring of phase transitions. It provides qualitative and quantitative speciation information for framework nuclei in glasses and is also capable of characterizing the dynamic behavior of mobile ions and solvent through relaxation, diffusion and chemical exchange experiments. Thus it has become an important technique for the study of hydrous minerals and gels and for ion-conducting glasses.

The sensitivity of NMR varies considerably, depending on the nucleus observed, its abundance and its chemical environment. NMR sensitivities and detection limits cannot compete with elemental analytical techniques such as X-ray fluorescence. In addition, quantitation in solids requires careful control of experimental parameters and careful calibration to avoid artifacts. However, the selectivity of NMR as an analytical technique is unsurpassed and the development of specialist pulse sequences to measure specific local interactions in solids makes it particularly well suited to the analysis of geological materials and glasses.

NMR imaging enables structural information to be resolved in three dimensions, although resolution in solid-state imaging is limited to tens of micrometers at best owing to the broader line widths and lower signal-to-noise ratios compared with liquids. However, capabilities in this field are being extended all the time and the application of NMR imaging techniques in materials analysis is expanding steadily. An alternative to conventional imaging is NMR force microscopy, which shows potential for surface mapping at higher resolutions.

The applications section is organized on the basis of the materials being analyzed. Within each section, NMR techniques are classified according to the observed nuclei. The emphasis is on more recent applications and on developments leading to enhanced resolution and sensitivity. Silicates and aluminosilicates represent...
the largest class of applications, followed by phosphate, borate and other oxide glasses. Sol–gel materials and the reactions leading to gel formation are also discussed, as are hydrous materials more generally. The other important areas of application reviewed are minerals, ceramics, high-temperature melts and ion-conducting glasses. Finally, the applications of NMR imaging in this field, although sparse at present, are potentially very great. This is illustrated by two major areas of application to date, namely the imaging of bone minerals and cement and concrete.

1 INTRODUCTION

1.1 Overview of Nuclear Magnetic Resonance Applications

NMR spectroscopy measures the transitions between nuclear spin energy levels in the presence of an external magnetic field. The energies of the transitions are sensitive to the local chemical environment of the nuclei. NMR spectroscopy can be applied to any nucleus having spin $I > 0$, although in practice some nuclei have low abundances and/or low sensitivities, making them difficult to observe, especially in solid samples. Wide-line spectra on static solids often consist of unresolved peaks or powder patterns whose line shape is sensitive to chemical shift anisotropy, dipole–dipole interactions and other interactions, moderated by molecular motion. High-resolution spectra of solids, achieved using a combination of magic-angle spinning (MAS) and specialist pulse sequences, provide compositional and structural information on the sample and in favorable cases on internuclear distances, while signal integration provides quantitation. In the solid state, the resolution is lower than in liquids, but NMR is still capable of resolving different species according to coordination number and ligand type, as exemplified by Si speciation in silicates, for which $^{29}$Si NMR is now the primary method.

NMR is particularly valuable in the analysis of amorphous and partially crystalline materials not amenable to structure determination by X-ray diffraction. NMR can detect and quantify materials containing multiple phases and can be used for in situ monitoring of phase transitions. It provides qualitative and quantitative speciation information for framework nuclei in glasses and is also capable of characterizing the dynamic behavior of mobile ions and solvents through relaxation, diffusion and chemical exchange experiments. Hence it has become an important technique for the study of hydrous minerals and gels and for ion-conducting glasses.

The sensitivity of NMR varies considerably, depending on the nucleus observed, its abundance and its chemical environment. NMR sensitivities and detection limits cannot compete with elemental analytical techniques such as X-ray fluorescence. In solids, between $10^{17}$ and $10^{20}$ nuclei are required, depending on the sensitivity of the nucleus, the temperature and the applied field. In addition, quantitation in solids requires rigorous control of experimental parameters and careful calibration to avoid artifacts. Since standard reference materials are rarely available for the sorts of materials being considered here, a combination of internal and external standards is needed for absolute concentrations to be obtained. However, the selectivity of NMR as an analytical technique is unsurpassed and the development of specialist pulse sequences to measure specific local interactions in solids makes it particularly well suited to the analysis of geological materials and glasses.

NMR spectroscopy can also be compared with vibrational spectroscopy (infrared and Raman) as a tool for structural determination in disordered materials. Vibrational spectroscopy is still an important complementary technique for the characterization of glasses. NMR spectra can be broadened considerably owing to paramagnetic components in the sample which do not affect the resolution of infrared or Raman spectra. Vibrational techniques are also easier to implement under conditions of high temperature and pressure.

NMR imaging enables structural information to be resolved in three dimensions, although resolution in solid-state imaging is limited to tens of micrometers at best, owing to the broader line widths and lower signal-to-noise ratios compared with liquids. However, capabilities in this field are being extended all the time and the application of NMR imaging techniques in materials analysis is expanding steadily. An alternative to conventional imaging is NMR force microscopy, which shows potential for surface mapping at higher resolutions.

The versatility of NMR and its ability to provide a unique combination of structural, dynamic and quantitative information are its main advantages in the analysis of geological materials and glasses.

1.2 Scope

This article concerns the application of NMR techniques to the analysis of geological materials and inorganic glasses. It has been necessary to be selective in the choice of applications, given the very broad scope of the field from the point of view of both the NMR techniques and the samples involved. The greatest emphasis has been placed on glasses and gels. We have included inorganic minerals but have not covered soils and clay minerals to any extent. The broad field of synthetic zeolites and mesoporous materials has been excluded, except to illustrate particular experimental points. Some solution-state NMR applications are...

3-D, three-dimensional; MRI, magnetic resonance imaging.

also described, for sol–gel reaction systems and high-temperature liquids and melts. The literature reviewed is primarily from 1993 onwards. A list of reviews covering NMR applications to glasses and minerals, along with relevant monographs, is given in Table 1, to provide access to earlier literature. In particular, the 1992 review by Eckert provides a comprehensive discussion of the literature on glasses up to that point, while NMR applications in mineralogy are reviewed in three monographs.

The applications section is organized on the basis of the materials being analyzed. Within each section, NMR techniques are classified according to the observed nuclei. The emphasis is on more recent applications and on developments leading to enhanced resolution and sensitivity. Silicates and aluminosilicates represent the largest class of applications, followed by phosphate, borate and other oxide glasses. Sol–gel materials and the reactions leading to gel formation are also discussed, as are hydrous materials more generally. The other important areas of application reviewed are minerals, ceramics, high-temperature melts and ion-conducting glasses. Finally, the applications of NMR imaging in this field, although sparse at present, are potentially very great. This is illustrated by two major areas of application to date, namely the imaging of bone minerals and cement and concrete.

2 EXPERIMENTAL ISSUES

2.1 Overview of Solid-state Nuclear Magnetic Resonance

NMR spectroscopy as a structural tool first found wide application when applied to molecules in the liquid phase. The technique involves measuring transitions between nuclear spin energy levels, and these transitions are in turn sensitive to the chemical environment in which the nuclei
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

are found. In the first forms of NMR spectroscopy to be developed, only liquid samples gave lines narrow enough to reveal directly chemical information. The Hamiltonian operator describing interactions of nuclear spins with an external field and with each other in the liquid state can be written according to Equation (1):

\[ H = H_Z + H_S + H_J \]  

(1)

where \( H_Z \) describes the nuclear Zeeman interaction, \( H_S \) is the magnetic shielding term and \( H_J \) is the indirect spin-spin coupling term.

The nuclear Zeeman interaction between the external magnetic field and the magnetic moment arising from the nuclear spin depends on the field strength and on the magnitude of the nuclear spin magnetic moment. There exist 117 stable naturally occurring isotopes with nonzero nuclear spins; the nuclear spin magnetic moments range in magnitude from 0.111 (\(^{187}\)Os) to 4.837 (\(^1\)H) in units of the nuclear Bohr magneton (the radioactive isotope \(^3\)H has a larger moment than that of the proton). Tables 2 and 3 list the properties of nuclei commonly studied in glasses and geological materials; these are divided into spin \( I = \frac{1}{2} \) and spin > \( \frac{1}{2} \) because of the importance of quadrupolar interactions discussed further below for nuclei with spin > \( \frac{1}{2} \). Tables 2 and 3 also list the frequencies at which NMR transitions are observed for different nuclei at a magnetic field strength of 7 T, a typical field strength used for solid-state NMR studies.

</table>
The sensitivity of a particular nucleus in the NMR experiment depends on the population difference between the spin states being excited, which in turn is a function of both the magnetic field strength and the magnetic moment of the nucleus. The larger the magnetic moment and the higher the magnetic field, the stronger the signal becomes. A third factor which may also be experimentally adjusted is the abundance of the particular isotope being examined. For example, $^{17}\text{O}$ is an isotope for which the NMR spectrum can give a great deal of structural information about oxide materials. With a natural abundance of 0.037%, however, the sensitivity is normally too low to be useful, but isotopic enrichment is frequently used to raise the sensitivity to observable levels (see examples in section 3). Tables 2 and 3 also include a relative sensitivity factor for each nucleus, which expresses the sensitivity relative to that of the proton, assuming that the isotope is present at natural abundance.

The magnetic shielding interaction $H_s$, more frequently referred to as the chemical shift, provides unique information about the chemical environment of the nucleus. It is due to the fact that electron density around the nucleus perturbs the magnetic field to a small extent, shifting the NMR frequency. Chemical shifts are usually reported in terms of a frequency shift from a reference compound divided by the resonance frequency of the reference compound, thus cancelling the effect of the nuclear Zeeman term. In the liquid phase, the chemical shift is averaged by rapid reorientation of molecules on the NMR timescale to give the isotropic value. The range of chemical shifts observed generally increases with the atomic number of the element concerned, e.g. from about 10 ppm for $^1\text{H}$ to 200 ppm for $^{13}\text{C}$ and 5000 ppm for $^{207}\text{Pb}$.

The indirect spin–spin coupling interaction between nuclear spins ($H_J$) is the result of coupling between nuclei and electrons in chemical bonds intervening between the atoms concerned. This interaction is extremely weak, typically a few hertz, but is routinely used as a powerful structural tool in high resolution liquid-phase NMR of complex molecules. The weakness of the interaction means that heteronuclear spin–spin coupling for molecules in the liquid phase is readily removed by low-power decoupling.

In solids, there are up to three additional interactions present which are not evident in liquid-phase spectra, and which cause dramatic increases in line width. First, the shielding interaction (chemical shift) is anisotropic, i.e. it depends on the orientation of the nuclear environment in the magnetic field. A low-symmetry nuclear environment (and it is the crystallographic site symmetry that is important rather than the molecular symmetry) will have its shielding described by three different principal components of the shielding or chemical shift tensor. If the environment has axial symmetry, two of the principal components will be equal (corresponding to the chemical shift when the field is perpendicular to the symmetry axis), and different from the third (the so-called parallel component). Only in the case of cubic symmetry will the chemical shift appear to be isotropic.

The consequence of shielding anisotropy for single-crystal samples is that the NMR frequency will vary with orientation of the crystal in the magnetic field. For polycrystalline powders or glasses, which contain randomly oriented nuclear environments, the NMR spectrum will be broadened over the frequency range corresponding to the chemical shift anisotropy. Figure 1(a–c) shows schematically the form of the so-called powder pattern expected for cubic, axial and nonaxial symmetry. A narrow line is obtained only for cubic symmetry. For the axial and nonaxial cases, the principal components of the shielding tensor can be deduced from the turning points in the spectrum.

The shielding anisotropy can yield useful information about the structure of the system being studied. In general, however, the spectral broadening caused by shielding anisotropy is perceived as degrading resolution, and MAS techniques are applied to remove it, as described below.

The second interaction present in solids which averages to zero in liquid-phase spectra is dipolar spin–spin coupling. The dipolar coupling interaction is the classical through-space interaction between two magnetic dipoles, which may both be the same nucleus (homonuclear dipolar coupling) or different (heteronuclear dipolar coupling). The magnitude of the interaction depends on the magnetic moments of the two nuclear spins, the distance between them and the orientation of the vector joining the spins in the magnetic field. The orientation dependence of the dipolar coupling is similar to that of the shielding anisotropy, i.e. dipolar coupling can also be
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

described by a second-rank tensor with three principal components. The spectra of powder or glassy samples in which dipolar coupling is present may contain broad poorly resolved lines. In samples which contain high concentrations of nuclei with large magnetic moments (such as $^1$H or $^{19}$F), the broadening caused by dipolar coupling may be as large as tens or hundreds of kilohertz, which will totally obscure any chemical shift information in the spectrum. Detection of such broad signals is also experimentally difficult. Developing efficient strategies for eliminating homonuclear dipolar coupling has been a major achievement of solid-state NMR in recent years. In other cases in which only heteronuclear dipolar coupling is present, high-power decoupling methods can be used to eliminate the interaction.

A third interaction present in the spectra of solids containing nuclei with spins $I > \frac{1}{2}$ is the nuclear quadrupole interaction. Nuclei with $I > \frac{1}{2}$ have a nonspherically symmetrical nuclear charge distribution producing a quadrupole moment. The interaction of this quadrupole moment with electric field gradients caused by asymmetric electron distributions in molecules or lattice sites perturbs the nuclear spin energy levels. For single-crystal samples, the quadrupole interaction causes a splitting of the single resonance into multiple components which will vary with orientation (depending on the symmetry of the electric field gradient). The magnitude of the interaction depends on the size of the quadrupole moment and the magnitude of the electric field gradient. If the interaction is small relative to the nuclear Zeeman term, it may be accurately described by first-order perturbation theory. In this treatment, the central ($\frac{1}{2} \leftrightarrow -\frac{1}{2}$) transition for nuclei with nonintegranal nuclear spins is unaffected by the quadrupole interaction. This transition will therefore still be observed in spectra of polycrystalline powders or glasses, whereas the satellite transitions, which are strongly orientation dependent, may be broadened beyond detection. Nuclei with integral spins will give broad powder patterns for all transitions, although the principle components of the quadrupole coupling tensor may be deduced from the turning points. Figure 2(a, b) illustrates hypothetical powder patterns for $I = 1$ and $\frac{3}{2}$ nuclei, assuming a first-order quadrupole perturbation.

When the quadrupole interaction becomes larger relative to the nuclear Zeeman term, a second-order perturbation treatment of the interaction must be used. In this case, even the central transition for nuclei with non-integral spin becomes anisotropic, and in polycrystalline or glassy samples gives a broad and complex line shape (Figure 2c). Note also that the centre of gravity of the spectrum is no longer at the isotropic chemical shift $\nu_0$. MAS (Figure 2d) does not completely remove the second-order quadrupolar broadening. More generally, spectra of quadrupolar nuclei in powders or glasses will have line shapes determined by both quadrupole interactions and chemical shift anisotropy, and computer simulation methods must be used to extract reliable parameters.

In summary, the Hamiltonian describing the interactions of nuclear spins in a solid sample contains five terms, four of which are anisotropic (Equation 2):

$$H = H_Z + H_a + H_J + H_D + H_Q$$

The indirect coupling term is normally (but not always) too small to be observed in solid-state NMR spectra. The remaining three terms all contribute to line width and loss of resolution in solid-state spectra; obtaining chemically informative isotropic chemical shift information from a solid sample therefore requires steps to be taken to remove the anisotropic interactions (so-called high-resolution solid-state NMR spectroscopy). On the other hand, the anisotropic interactions contain a great deal of additional structural information. A second development in solid-state NMR spectroscopy has been the development of techniques which allow that additional information to be extracted. Both approaches are illustrated below.

2.2 Static (Wide-line Nuclear Magnetic Resonance) of Solids

Historically, NMR spectra of solids were first detected using continuous wave (CW) techniques; either the detector response was measured as the radiofrequency (RF)
or the magnetic field was swept through resonance under slow passage conditions. The sensitivity is inherently low, however, and instruments capable of performing this experiment are no longer commercially available.

The application of pulse NMR techniques dramatically improved the sensitivity and versatility of NMR spectroscopy applied to liquid-phase samples with inherently narrow lines. The broad lines typical of solids are, however, much more difficult to measure accurately using pulse techniques. In a conventional one-pulse experiment, where a single pulse is followed by measurement of the free induction decay (FID), a significant fraction of the FID from a broad solid spectrum will be lost in the receiver deadtime immediately following the pulse. Fourier transformation of such an FID will give an inaccurate depiction of the spectrum. The deadtime problem can be overcome by Fourier transforming the decay of a spin echo; a number of different echo-generating pulse sequences have been used for this purpose. Figure 3(a) and (b) shows, for example, static $^{27}$Al NMR spectra of $\alpha$-alumina measured by single-pulse and spin echo acquisition. The single-pulse experiment allows the turning points expected in the powder pattern for an $I = \frac{1}{2}$ nucleus to be correctly recorded, but does not correctly display the intervening intensity. The spectrum acquired by Fourier transformation of the spin echo decay gives a much better (although still not completely accurate) depiction of the true line shape.

No single-pulse or echo measurement will allow correct line shapes to be recorded for lines broader than about 200 kHz. This limitation arises from the maximum excitation bandwidth achievable with a conventional high-power pulse. Excitation by composite pulses or shaped pulses may achieve some small improvement in bandwidth. The alternative approach for broad lines is to measure the spectrum conventionally or using echoes at a series of different frequencies or fields (i.e. to combine the advantages of the old CW technique with those of the pulse experiment). For example, Bastow and Smith(7) obtained a broad-line $^{91}$Zr spectrum of ZrO$_2$ by measuring the spin echo amplitude at many different excitation frequencies to map out the line shape. This is, however, a tedious experiment requiring retuning of the probe between each point. Alternatively, the magnetic field may be swept. Poplett and Smith(8) recently described an instrument containing a superconducting magnet which could be swept over a field range of 1 T; this allowed $^{27}$Al spectra with line widths beyond 3 MHz to be accurately measured.

### 2.3 Magic-angle Spinning for $I = \frac{1}{2}$ Nuclei

The terms in the dipolar coupling Hamiltonian and the anisotropic component of the shielding Hamiltonian both contain the geometric factor $3\cos^2\theta - 1$, where $\theta$ describes the orientation with respect to the magnetic field. In the liquid phase, rapid isotropic molecular tumbling averages this factor to zero, so that dipolar coupling and shielding (chemical shift) anisotropy vanish. A similar averaging can in principle be achieved by rotating a solid sample rapidly about an axis making an angle of 54.7° to the magnetic field (the angle at which $3\cos^2\theta - 1 = 0$). In the case of dipolar coupling, the rotation frequency must exceed the magnitude of the coupling. Since this may be hundreds of kilohertz, and practically feasible sample rotation frequencies are limited to $<20$ kHz, the MAS technique is not generally used for the removal of dipolar broadening. Broadening due to chemical shift anisotropy, however, may often be small enough in magnitude to qualify for this technique. Figure 4 shows, for example, the
31P spectrum of solid WO3·P2O5 measured at different MAS spinning speeds. The static spectrum shows a typical powder pattern for an axially symmetric chemical shift tensor, with a total anisotropy of ca. 40 ppm or 6000 Hz. When the sample is spun at the magic angle at a frequency of 6000 Hz, the spectrum collapses to a single line at the isotropic value of the chemical shift. At lower spinning speeds, spinning side bands are seen which trace out approximately the intensity profile of the powder pattern, and which are separated by the spinning frequency.

Following the first introduction of a commercial MAS probe in 1978, the design and performance of such probes has steadily improved and routine spinning of solid samples at frequencies of 18 kHz or higher under computer control is now feasible. This achieves removal of chemical shift anisotropy from spectra of lower atomic number elements although, as noted above, heavier elements such as 207Pb may show too large an anisotropy to be fully removed. Where MAS does not totally remove chemical shift anisotropy, the intensity distribution of the spinning sidebands can be analyzed to deduce the principal components of the chemical shift tensor. Pulse sequences are also available for suppressing the spinning side bands. The effects of MAS on spectra of quadrupolar nuclei are discussed in section 2.8.

2.4 Cross-polarization

The technique of cross-polarization (CP) is usually coupled with MAS in measuring the spectra of magnetically dilute nuclei, to enhance sensitivity. This is achieved in two ways: by transferring magnetization from a more abundant nucleus to the dilute nucleus of interest, and by shortening the spin–lattice relaxation time allowing faster pulse repetition and thereby achieving a better signal-to-noise ratio in a given measurement period. Detailed accounts of CP and the pulse sequences used are given elsewhere. The key to successful CP is strong dipolar coupling between the abundant nucleus and the nucleus being measured. The abundant spin is first spin locked in the rotating frame, where it oscillates at a frequency controlled by the RF field strength. The dilute spin is then rotated in the rotating frame at a frequency matching that of the abundant spin, allowing spin flip transitions to occur and magnetization of the dilute spin to grow. The RF excitation of the dilute spin is then turned off, and its FID measured. The RF excitation of the abundant spin remains on during the FID acquisition, to decouple heteronuclear dipolar interactions between the two spins. The delay between successive pulses and FID acquisitions is now determined by the spin–lattice relaxation time of the abundant nucleus, rather than that of the dilute nucleus.

The efficiency of CP is determined by the extent of dipolar coupling and the rate of spin diffusion of the abundant nucleus, which causes loss of the spin-locked signal. The balance achieved between these two competing processes will determine the extent to which enhancement of signal intensity occurs. Optimum CP requires the abundant nucleus to have a relatively long spin diffusion rate (characterized by $T_{1r}$, the relaxation time in the rotating frame) and a relatively short spin–lattice relaxation time.

CP is usually combined with MAS, which can cause some difficulties. As noted above, MAS will tend to average the dipolar coupling interaction to zero. If it were to do this completely, the efficiency of CP would fall to zero. In practice, the MAS spinning rate is rarely fast enough to eliminate dipolar coupling; nevertheless, it can greatly reduce the efficiency of CP. There is therefore an incentive to avoid high-speed MAS when carrying out CP.
Alternatively, a recently introduced variable-amplitude cross-polarization (VACP) experiment appears to offer promise for efficient CP at high MAS frequencies.\(^\text{13}\) CP has been widely used in \(^{13}\mathrm{C}\) NMR studies of organic compounds, where abundant protons transfer magnetization to dilute \(^{13}\mathrm{C}\). The technique can, however, be used in principle with any dilute spin system. For example, in \(^{29}\mathrm{Si}\) NMR of silica gels and glasses, \(^{1}\mathrm{H}\) CP will selectively enhance only the signals due to Si atoms which are close to protons (i.e. SiOH groups).

### 2.5 Dipolar Decoupling

Removal of the heteronuclear dipolar coupling contribution to line broadening in the NMR spectra of solids is similar in principle to the decoupling process in liquid-phase NMR: the second nucleus is irradiated at its NMR frequency with sufficient power to saturate the resonance, reducing the magnetic moment of the second nucleus effectively to zero. Because the dipolar coupling is much larger in magnitude than the indirect (scalar) coupling found in the liquid phase, the power levels needed to achieve effective heteronuclear decoupling in the solid state are considerably higher than those in liquid samples. Effective decoupling requires the continuous application of an RF field to the second nucleus during acquisition of the FID from the nucleus of interest. This can entail transmitter power levels of 1 kW or higher, which created some experimental difficulties during the early development of solid-state NMR, but which is now routinely available. Such high-power decoupling also eliminates the indirect heteronuclear coupling interaction although, as noted above, this is normally too weak to have a significant impact on line widths.

High-power decoupling cannot be used to eliminate the homonuclear dipolar coupling interaction which dominates the NMR spectra of solids containing magnetically abundant nuclei in close proximity (particularly \(^{1}\mathrm{H}\) and \(^{19}\mathrm{F}\)). This interaction is generally too strong to be removed by MAS; although the angular dependence of the dipolar coupling interaction is identical with that of the chemical shift anisotropy, spinning speeds needed to eliminate dipolar broadening cannot normally be realized. One chemical approach to the problem is to achieve magnetic dilution by selective isotopic labeling. For example, substitution of \(^{1}\mathrm{H}\) by \(^{2}\mathrm{H}\) in selective sites allows measurement of quadrupolar line shapes in the proton decoupled \(^{2}\mathrm{H}\) NMR spectrum, which give information about molecular order and dynamics. Examples of such \(^{2}\mathrm{H}\) NMR studies are described below. Generally however, such chemical modification may cause structural changes to the system of interest, and therefore cannot compete with physical decoupling methods.

Physical decoupling of the homonuclear dipolar coupling interaction can be achieved with multiple pulse sequences. These consist of a cycle of RF pulses which is applied repetitively to the spin system. Qualitatively, such a sequence can be visualized as rotating the spin magnetic moments in spin space rather than laboratory space, achieving a similar averaging of the dipolar coupling interaction to zero to that found in liquid samples. For example, the so-called Waugh–Huber–Haeberlin (WAHUHA) four pulse sequence applies successive \(90^\circ\) pulses about the \(x\), \(-x\), \(y\) and \(-y\) axes in the rotating frame, with suitable delays between. This can be visualized as forcing the spins to spend equal times oriented along the \(x\), \(y\) and \(z\) axes in the rotating frame, which produces the same average effect as alignment along the MAS axis.

A more correct and quantitative description of multiple pulse averaging requires the use of density operator theory to solve the time-dependent Schrödinger equation, which will not be undertaken here. Increasing the number of pulses and varying their phases can achieve averaging of the dipolar coupling interaction to higher order and compensate for magnetic field inhomogeneities and finite pulse lengths. Since the entire pulse sequence must be applied between the acquisition of each point in the FID, the need to generate precisely timed sequences of extremely short pulses places formidable demands on pulse generation and pulse timing hardware. The technique has nevertheless now become readily available on commercial instruments. The combination of multiple pulse averaging of homonuclear dipolar coupling and MAS to remove chemical shift anisotropy has become known as combined rotation and multiple pulse spectroscopy (CRAMPS); this method for achieving high-resolution solid-state spectra is now widely used for \(^{1}\mathrm{H}\)- and \(^{19}\mathrm{F}\)-containing solids.\(^\text{14}\)

### 2.6 Chemical Shift Correlation Experiments

Correlation spectroscopy is a two-dimensional (2-D) NMR experiment which produces correlation diagrams describing relationships between spectral features. Such 2-D correlations have been used for many years in liquid-phase NMR to determine molecular structure; more recently the techniques have also been applied to solids. Conventional one-dimensional (1-D) NMR involves conversion of the time domain signal following an RF pulse (the FID) into a frequency domain spectrum by Fourier transformation. For many pulse sequences, however, the FID may also depend on a second time variable (e.g. the delay between two successive pulses), which is known as the evolution period. If this second time variable is designated \(t_1\) and the acquisition time of the FID (the detection period) is \(t_2\), then the FID is a
function of both $t_1$ and $t_2$. If the experiment is carried out to measure the FID at many different $t_1$ values, the resulting data set will be a 2-D array in which the FID intensity depends on $t_1$ and $t_2$. Fourier transformation in both dimensions will then yield a 2-D spectrum which can be plotted in three dimensions as intensity versus the two frequency components $f_1$ and $f_2$. The significance of $f_1$ and $f_2$ will depend on the particular pulse sequences employed.

The interaction between nuclei on two sites with different chemical environments may be through chemical bonds (scalar or $J$-coupling) or through space (dipolar coupling). Although the scalar coupling interaction is too weak to be normally resolved in conventional 1-D spectra of solids, the interaction can nevertheless be used to establish correlations between nuclei which are linked by chemical bonds. For example, the so-called COSY (correlated spectroscopy) experiment involves measuring the FID following two successive 90° pulses separated by the evolution time $t_1$. During the evolution period, magnetization is transferred between spins which are scalar coupled, modulating the subsequent FID. The 2-D spectrum obtained by double Fourier transformation is a plot of intensity versus chemical shift in both dimensions. Figure 5 shows, for example, the $^{29}$Si COSY spectrum of $^{29}$Si-enriched zeolite ZSM-39 reported by Fyfe et al. in 1989. The peaks along the diagonal axis correspond to the normal 1-D spectrum of this material, which contains three distinct silicon sites. The cross peaks arise from scalar coupling between $^{29}$Si nuclei on different sites. In this case, sites 1 and 2 are coupled, as are sites 2 and 3, establishing the connectivity through oxygen between the sites. Because of the low natural abundance of $^{29}$Si (Table 2), initial COSY experiments used isotopically enriched samples, although this was later shown not to be absolutely necessary. Signal enhancement was also achieved by exploiting CP from protons of organic template molecules within the zeolite.

An alternative correlation experiment which does not require isotopic enrichment is INADEQUATE (incredible natural abundance double quantum transfer experiment). This experiment was first introduced to establish $^{13}$C–$^{13}$C connectivities in organic compounds at natural abundance levels, but it can also be applied to $^{29}$Si in solids. The result of an INADEQUATE experiment is a 2-D plot in which only cross peaks are present at positions corresponding to the chemical shifts of nuclei which are scalar coupled to each other. Compared with COSY, the INADEQUATE experiment has the considerable advantage that there are no intense peaks on the diagonal, making it easier to observe connectivities between closely spaced resonances. However, implementing the optimum pulse sequence for an INADEQUATE experiment requires knowledge (or at least a reasonable estimate) of the scalar coupling constant, which is not resolved in the 1-D spectrum. Fyfe et al. determined the Si–O–Si $J$ coupling constant in zeolites to be about 10 Hz (from observed splittings in COSY experiments with isotopically enriched samples).

### 2.7 Double-resonance Experiments

Information about connectivities or proximities between different nuclei in solid samples can be obtained from a variety of different double-resonance experiments. These experiments rely on the heteronuclear dipolar coupling between spins to establish their proximity in a sample. For example, the SEDOR (spin echo double resonance) experiment determines the dipolar coupling constant for a static sample by applying a 180° pulse to the second nucleus during a spin echo pulse sequence applied to the first nucleus. This has the effect of inverting the sign of the dipolar coupling between the two nuclei, reducing the echo amplitude. From a plot of spin echo intensity
versus echo time or pulse position, the dipolar coupling constant can be obtained. From the dipolar coupling constant, the internuclear distance is calculated.\(^{(16)}\) The REDOR (rotational echo double resonance) experiment is obtained by combining SEDOR with MAS. MAS greatly enhances sensitivity and resolution; a sequence of rotor synchronized 180° pulses is applied to the second nucleus during a spin echo sequence, and the echo amplitude is attenuated by the dipolar coupling. The dipolar coupling constant (and hence the internuclear distance) is obtained by measuring the echo amplitude as a function of the position of rotor periods or of the position of the 180° pulses.\(^{(17)}\)

Both SEDOR and REDOR are difference experiments, where the echo intensity decrease is a measure of the dipolar coupling. TEDOR (transferred echo double resonance), on the other hand, measures an intensity increase. The TEDOR experiment is essentially comprised of two REDOR pulse sequences applied to both spin systems in succession. The echo intensity for the second spin is measured as a function of the number of MAS rotor cycles or as a function of the position of the 180° pulses.\(^{(18)}\)

The determination of internuclear distances from such 1-D double resonance experiments is readily achieved if the sample contains isolated pairs of spins. In the more usual situation where a nucleus may be coupled to a number of neighboring nuclei at different distances, interpretation of TEDOR or REDOR curves becomes more difficult, and it may become necessary to assume a particular structural model in order to extract distance information.

A qualitative double resonance experiment applicable to quadrupolar nuclei is TRAPDOR (triple resonance adiabatic passage double resonance). This still involves modulation of the heteronuclear dipolar coupling to attenuate an echo signal, as in TEDOR, but uses continuous irradiation of the second (quadrupolar) spin during the spin echo sequence applied to the first nucleus (which may or may not be quadrupolar). A TRAPDOR experiment allows the qualitative determination of which sites in a multicOMPONENT spectrum are dipolar coupled to a quadrupolar nucleus, but no distance information can be obtained.\(^{(19)}\)

2-D heteronuclear correlation experiments can be used to provide connectivity information in a similar manner to the homonuclear COSY experiment described above. In the so-called HETCOR (heteronuclear correlation spectroscopy) experiment, magnetization is transferred between the two spin systems during the evolution period by either CP or TEDOR. The resulting 2-D spectrum shows cross peaks for nuclei which are dipolar coupled.\(^{(20)}\)

### 2.8 Sample Spinning Experiments with Quadrupolar Nuclei

As noted above, the central (\(\frac{1}{2} \leftrightarrow -\frac{1}{2}\)) transition in the spectra of nonintegral quadrupolar nuclei is independent of sample orientation to first order, so that this contribution to the spectrum is not broadened in polycrystalline or glassy samples. The second-order quadrupolar interaction is anisotropic, however, and the angular dependence involves two different Legendre polynomials such that there is no one orientation about which the interaction can be averaged to zero. Conventional MAS will remove the \(3 \cos^2 \theta - 1\) component of the second-order quadrupolar broadening, and narrow but not totally remove the other component. The spinning speed needed to achieve this depends on the magnitude of the quadrupolar coupling and the magnetic field at which the spectrum is measured (since the second-order broadening depends on the relative magnitudes of the quadrupolar and Zeeman interactions). For an \(I = \frac{3}{2}\) nucleus such as 27Al, for example, the maximum quadrupolar coupling interaction which can be narrowed by MAS is given by Equation (3):

\[
C_q = 8.82 (v_{R-V})^{1/2}
\]

Thus, in a 7-T magnet, spinning at 10 kHz will narrow 27Al lines with a quadrupolar coupling constant of up to 7.78 MHz. In a 14-T magnet, on the other hand, spinning at 18 kHz will reduce the line width for coupling of up to 14.7 MHz. There is therefore an incentive to record MAS spectra of quadrupolar nuclei with nonintegral spins in as high a magnetic field as possible, with the fastest spinning speed possible, in order to narrow the central transition as much as possible; 18 kHz MAS speeds are now routinely possible, and speeds as high as 35 kHz have been reported.\(^{(21)}\)

A second consequence of the second-order quadrupolar interaction is that the center of gravity of the narrowed central transition in the MAS spectrum will not correspond to the isotropic chemical shift. Only in the limit of very high magnetic field where the second-order quadrupolar interaction vanishes will the peak position become exactly the isotropic chemical shift. For example, the apparent chemical shift in the 27Al MAS spectrum of kaolinite varies from 36 ppm at 3.5 T to -8 ppm at 14 T.\(^{(5)}\) This provides a further incentive to measure spectra of quadrupolar nuclei at as high a field as possible if accurate chemical shifts are to be obtained, and to measure spectra at two different magnetic fields to check for the presence of any second-order shift.

Complete removal of the second-order quadrupolar interaction would allow in principle the accurate determination of isotropic chemical shifts and the resolution of small chemical shift differences. Spinning about a single axis cannot achieve this, but spinning about two axes...
simultaneously. The so-called double angle rotation (DOR) technique achieves this by enclosing a spinning rotor within a second spinning rotor such that the axis of rotation of the inner rotor describes a well-defined trajectory as a function of time. The second-order quadrupolar frequency of the central transition then experiences a double modulation in the laboratory frame instead of the single modulation imposed by conventional MAS. The two angles at which the rotors spin are chosen to null the two different angular components of the second order quadrupolar interaction (e.g., $54.74^\circ$ and $30.56^\circ$ or $70.15^\circ$).\(^{22}\) There are severe experimental difficulties in achieving stable spinning of such a double rotor, and the effectiveness of the technique is restricted by the relatively slow spinning speed that can be achieved in the outer rotor (which produces extensive spinning side band patterns). Nevertheless, the technique has been very successful in resolving chemical shift information in a number of cases.\(^{23}\)

An alternative to DOR which avoids the mechanical complexity and expense of a double rotation MAS probe is so-called dynamic angle spinning (DAS). This is a 2-D technique in which the orientation of the sample rotation axis is different for every evolution period.\(^{24}\) The resonance frequency of a spin when rotating at one orientation is correlated with its frequency when rotating at a second angle. A mathematical justification of how such a correlation can be used to eliminate second-order quadrupolar broadening of the central transition for nonintegral spins was given by Grandinetti.\(^{25}\) The two angles are chosen to satisfy simultaneously Equations (4) and (5):

\[
P_2(\cos \theta_1) = -kP_2(\cos \theta_2) \quad (4)
\]
\[
P_4(\cos \theta_1) = -kP_4(\cos \theta_2) \quad (5)
\]

where $P_2$ and $P_4$ are the second- and fourth-order Legendre polynomials (responsible for the angular dependence of the first- and second-order quadrupolar interaction, respectively), and $k$ is a scaling factor. There is a continuous set of solutions for these equations, each with a different scaling factor. For these solutions, the second-order powder pattern at one angle is an exact mirror image of that at the other angle. If the time at the first orientation is $t_1$, an echo will form at time $t_2 = kt_1$ which is isotropic. By collecting the intensity of the echo maxima as a function of $t_1$ and Fourier transforming the resulting interferogram, an isotropic DAS spectrum is obtained. Alternatively, the complete echo is acquired as a function of $t_1$ and the resulting 2-D spectrum is subjected to a so-called shearing transform to display the isotropic spectrum.

The DAS experiment requires a probe in which the rotation angle can be switched quickly and reproducibly (e.g., in <10 ms). The technique, being 2-D, involves much longer acquisition times than simple MAS or DOR, and it cannot be applied to systems having short $T_1$ values (which will show a substantial loss of intensity during the time taken to reorient the rotation axis). Nevertheless, it has been widely applied to nuclei such as $^{17}$O.

2.9 Other Techniques for Quadrupolar Nuclei

Quadrupole nutation NMR is a 2-D experiment introduced by Kundla et al.\(^{26}\) to separate quadrupolar interactions from other line broadening interactions. The spin system is allowed to evolve in time for a period $t_1$ in which both the RF and quadrupolar interactions are present, then for a period $t_2$ in which only the quadrupolar interaction is present. An FID is acquired during $t_2$ as a function of the RF pulse length $t_1$. Double Fourier transformation gives a 2-D spectrum in which the $F_2$ projection is the normal powder pattern showing second-order quadrupolar broadening and chemical shift anisotropy, and the $F_1$ projection is the so-called nutation spectrum which contains contributions only from quadrupolar interactions and is independent of chemical shift. The technique thus allows discrimination between species with similar chemical shifts but different quadrupolar interactions. The nutation spectrum can, however, be a complex pattern which is difficult to interpret, and computer simulation is often used to assist.\(^{27}\)

A new experiment which was first reported in 1995 shows great promise for solid-state NMR studies of quadrupolar nuclei. The 2-D multiple quantum magic-angle spinning (MQMAS) experiment enhances resolution of the spectra of half integral quadrupolar nuclei. The experiment correlates the $(\frac{1}{2} \leftrightarrow -\frac{1}{2})$ single quantum transition to the $(m \leftrightarrow -m)$ multiple quantum transition. The quadrupole frequencies of both transitions are correlated; thus the anisotropic parts of the quadrupole interaction are refocused, forming an echo. In one form of the experiment, the multiple quantum transition is excited by a single high-power RF pulse, and the multiple quantum coherence allowed to evolve for a period $t_1$ before a second pulse is applied, which converts the multiple quantum coherence into a single quantum coherence which is observed during $t_2$. The resulting 2-D spectrum obtained by measuring the FID acquired in $t_2$ as a function of $t_1$ can be processed to yield both the isotropic chemical shifts and the second order quadrupole induced shifts.

Figure 6 shows, for example, the triple quantum $^{17}$O 2-D MQMAS spectrum of albite glass. This material contains Si–O–Si and Si–O–Al bridging oxide ions. In the normal 1-D MAS experiment, the signals from these two species overlap and cannot be separated. In the 2-D MQMAS experiment, however, the 2-D plot shows clear
NUCLEAR MAGNETIC RESONANCE OF GEOLOGICAL MATERIALS AND GLASSES

resolution of the two types of oxygen, and the quadrupole coupling parameters for both can be obtained.\textsuperscript{29}

Many different schemes and strategies for acquiring MQMAS spectra and processing the data obtained have been described,\textsuperscript{5} and the technique will undoubtedly find growing applications in the area of glasses and geological materials. Comparisons of MQMAS with the earlier techniques (DOR and DAS) have been reported.\textsuperscript{30–32}

2.10 Nuclear Magnetic Resonance Experiments at High Temperature

High-temperature NMR measurements present particular challenges. The technical details are not presented here but are reviewed elsewhere.\textsuperscript{1,3,33} Static (wideline) NMR experiments allow temperatures up to about 1700 °C to be reached, while MAS above 600 °C is possible with a heated gas flow, but is still nonroutine. Laser heating allows even higher temperatures to be achieved (up to 2500 °C), although this approach presents other challenges such as controlling the homogeneity of heating, temperature calibration and the possibility of inducing changes in the sample or loss of sample during heating.

The sensitivity of the NMR experiment is reduced at higher temperatures owing to the less favorable Boltzmann population of the excited states, but this can be partly offset by reduced line widths in both liquids and solids due to increased mobility.\textsuperscript{33}

2.11 Quantitative Solid-state Nuclear Magnetic Resonance

In many NMR experiments the signal intensity does not correlate quantitatively with the number of nuclei in the sample. This is especially the case in heterogeneous solids, although under carefully controlled conditions it is possible for signal integration to be quantitative. There are a number of contributing factors. First, for broad line signals in solids not all nuclei may be uniformly excited. Small flip-angle pulses can be used to ensure uniform response across the signal.\textsuperscript{5} In samples with a wide range of relaxation times, some nuclei may relax too quickly (or too slowly) to be observed under the experimental conditions. In single-pulse wideline experiments there will be significant signal loss during the dead-time of the receiver. Even with MAS, if line widths are large as they are in glasses, this will remain a problem and differential signal loss may be obtained across the spectrum. Variable delays before signal acquisition can be used to detect the problem and in some cases to extrapolate back to 100% signal intensities, although this will not compensate for signals which have completely relaxed before detection can begin. Spin-echo techniques can be used to avoid the dead-time problem. Recycle delay times must also be long enough to avoid saturation of nuclei with long spin–lattice relaxation times. This may ultimately limit sensitivity by increasing acquisition times.

Internal standards have been used to calibrate changes in signal intensity in single-pulse experiments. A recent example is the use of AIN as the internal standard to calibrate the detected Al signals in as-synthesized versus calcined MCM-41\textsuperscript{34} (Figure 7).

![Figure 6](image_url) **Figure 6** Triple quantum $^{17}$O 2-D MQMAS spectrum of albite glass ($^{17}$O enriched). [Reproduced with permission from Dirken et al.\textsuperscript{29}]

![Figure 7](image_url) **Figure 7** $^{27}$Al NMR signals in as-synthesized versus calcined MCM-41a acquired using AlN as an internal standard. [Reproduced with permission from Janicke et al.\textsuperscript{34}]
The determination of crystalline silica in iron oxide pigments provides a good example of the experimental considerations required for calibration in $^{29}$Si NMR. Single-pulse excitation with MAS spinning was used. Because of the long $T_1$ relaxation times for the silica, a reduced pulse angle of $10^\circ$ with a 20-min relaxation delay between acquisitions was required. A blind test of silica standards was used for comparison, with X-ray diffraction analyses as a test of the protocol and tetrakis(trimethylsilyl)silane was employed as the spin-counting standard.

The use of CP to transfer magnetization from abundant to dilute nuclei leads to enhanced sensitivity but also to quantitation problems because the CP efficiency varies with the strength of the heteronuclear dipolar coupling. Combined with variations in proton relaxation times in the rotating frame ($T_1^*$) and added difficulties at high MAS speeds, quantitative transfer of excitation is difficult. Detailed characterization of contact times and relaxation properties must be carried out and CP is often not used if quantitative analysis is required. A linear ramp of CP amplitudes in combination with high-speed MAS has been shown to improve quantitation in $^1$H–$^{13}$C cross-polarization/magic-angle spinning (CPMAS) experiments.

For quadrupolar nuclei of half-integer spin, there are additional complications, since it may be only the central transition that can be accurately observed. However, techniques for the correction of the center band to obtain the total signal intensity have been investigated. The current state-of-the-art for the quantitation of half-integer quadrupolar nuclei has been recently reviewed by Smith and van Eck. Finally, even when all experimental precautions have been taken, there remains the question of whether deconvolution of overlapping signals in order to obtain quantitative speciation in amorphous samples is valid. The deconvolution issue has been critically reviewed for $^{29}$Si Q$^*$ speciation in silicates but the concerns raised are likely to be just as significant for speciation of other nuclei. Factor analysis has also been evaluated for separating the spectral components in $^{113}$Cd MAS spectra consisting of overlapping isotropic peaks and is proposed as superior to least-squares fitting methods.

The other issues of interest to analytical chemists are those of sensitivity and detection limit. As a point of comparison, it is interesting to compare the detection levels reported recently for silicone species by $^{29}$Si distortionless enhancement by polarization transfer (DEPT) NMR in solution with detection limits for elemental methods of analysis such as inductively coupled plasma atomic emission spectrometry (ICP-AES) or inductively coupled plasma mass spectrometry (ICP-MS). On a standard commercial 17.61 T instrument, using an unenriched sample of hexamethyldisiloxane, the $^{29}$Si detection limit was 150 ng mL$^{-1}$, requiring an acquisition time of 52 h. For solids it is more difficult to generalize on the question of detection limits in NMR experiments, except that they will be substantially larger than those in solution. The sensitivity of an NMR experiment depends primarily on the nucleus (its abundance, gyromagnetic ratio and quadrupole moment) and on the applied magnetic field and temperature. However, it is also affected by symmetry and relaxation effects in the sample. The concentrations of species which can be detected for a particular nucleus in the solid state depend therefore on both instrumental and sample matrix considerations, but between $10^{17}$ and $10^{20}$ spins are generally required. It should also be noted that capabilities of NMR for the detection of low concentrations are continually being improved.

2.12 Nuclear Magnetic Resonance Relaxation Experiments

2.12.1 Spin–Lattice Relaxation

When the nuclear spins in a sample are excited with an RF pulse, a magnetization $M_0$ develops along the direction of the magnetic field. This magnetization relaxes exponentially back to the equilibrium value $M_0$. This process is called longitudinal or spin–lattice relaxation. It involves loss of excitation energy to the surrounding lattice and is characterized, at least in mobile liquids, by a single relaxation time $T_1$, the spin–lattice relaxation time. Spin–lattice relaxation can occur by a number of different mechanisms, but all require fluctuations in the local environment of the nucleus at frequencies comparable to the Larmor frequency, $\omega_0$. Thus spin–lattice relaxation is sensitive to atomic and molecular motion and is used as a probe of mobility in both liquids and solids. Spin–$\frac{1}{2}$ nuclei relax predominantly by dipolar interactions, whereas in quadrupolar nuclei ($I > \frac{1}{2}$) interactions with fluctuating electric field gradients contribute to relaxation. Detailed discussion of relaxation mechanisms is given in many NMR texts and monographs and is not repeated here. In simple systems, the relationship between the relaxation rate $1/T_1$ and the correlation time for molecular motion $\tau_c$ is given by Equation (6):

$$\frac{1}{T_1} = \text{constant} \times \frac{\tau_c}{1 + \omega_0^2 \tau_c^2} \quad (6)$$

In solids, where mobility is low and $\tau_c \gg 1/\omega_0$, $T_1$ decreases with increasing temperature. A minimum in $T_1$ is reached when $\tau_c \approx 1/\omega_0$ and relaxation becomes slower again as mobility increases further. In the motional narrowing region, where $\tau_c \gg 1/\omega_0$, $T_1$ shows...
the reverse temperature dependence. This is illustrated by results for $^7\text{Li}$ spin–lattice relaxation in Li$_2$SO$_4$ (Figure 8).\textsuperscript{42}

If the temperature dependence of $\tau_c$ follows Arrhenius-type behavior with an activation energy $E_a$, then $T_1$ data can be used to extract the activation energy. This is often assumed as a model for interpreting $T_1$ versus inverse temperature both above and below the $T_1$ minimum. Not surprisingly, in many samples, and especially in glasses, deviations from this simple model are observed since assumptions of single correlation times are unlikely to be valid. For the Li$_2$SO$_4$ example shown in Figure 8, although the individual $^7\text{Li}$ relaxation times were well fitted by single exponential fits, the Arrhenius plot was asymmetric, indicating different apparent activation energies in the fast and slow motion regions.\textsuperscript{42} This effect is commonly observed in ion-conducting materials.

Apart from its utility as a probe of local motion, a knowledge of relaxation behavior is important for measuring NMR spectra. A recycle delay of $5T_1$ is needed between pulse sequences to avoid saturating the signals of slowly relaxing nuclei. On the other hand, if relaxation is too fast, this contributes to line broadening. Spin–lattice relaxation times are generally measured by the inversion–recovery pulse sequence $180^\circ – \tau – 90^\circ$. It can be difficult to excite broad signals uniformly in solids with a $180^\circ$ pulse and an alternative method, saturation recovery, $(90^\circ)_n – t_1 – 90^\circ$, can be used.\textsuperscript{40} Relaxation time can also be used as the basis for contrast in NMR imaging.\textsuperscript{41}

2.12.2 Spin–Spin Relaxation

When the spins in the sample are subjected to a $90^\circ$ pulse, the $z$ magnetization is rotated into the $xy$ plane. The decay of this magnetization in the $xy$ plane is known as transverse or spin–spin relaxation. It corresponds to an exchange of energy among nuclei with slightly different resonance frequencies. The RF signal in the $xy$ plane gradually loses phase coherence and decays to zero and this is seen directly in the decay of the FID. The spin–spin relaxation time directly affects the line width of the NMR signal and estimates of $T_2$ can be obtained from the line width at half-height. $T_2$ is generally measured using modifications of the Carr–Purcell pulse sequence.\textsuperscript{40} In liquids, under motional narrowing conditions, $T_1 = T_2$. However, in solids $T_2$ will be much shorter than $T_1$. Complex relaxation behavior is also observed for liquids in confined-pore materials.\textsuperscript{41}

2.12.3 Spin–Lattice Relaxation in the Rotating Frame

Under conditions of CP, the abundant spin is locked in the rotating frame. The rate at which the magnetization in the rotating frame decays is characterized by a relaxation time $T_{1p}$, and is sensitive to fluctuating local fields in the kilohertz range. In CP experiments, $T_{1p}$ for the abundant spins can be determined from plots of signal intensity versus contact time. An initial increase in intensity is observed determined by the CP time constant, with a decay in signal intensity at longer contact times due to rotating frame relaxation. The efficiency of CP in solids thus depends on the relative rates of these two processes. In $^{29}\text{Si}$–$^1\text{H}$ CP in silicates or aluminosilicates, for example, the proton concentrations may be low, making $T_{1\text{SiH}}$ relatively long and comparable to the proton $T_{1p}$. This affects the maximum $^{29}\text{Si}$ intensity which can be achieved and hence limits the sensitivity of the experiment. In heterogeneous systems, a single $T_{1p}$ may not always be found and this can provide evidence for the existence of multiple phases since the relaxation is not averaged by spin diffusion.

2.13 Magnetic Resonance Imaging

MRI, like NMR spectroscopy itself, is not a single technique but covers a wide range of capabilities from qualitative imaging of fluids based on relaxation contrast to parameter mapping, where quantitative 3-D maps of specific parameters such as relaxation time or spin density are obtained.\textsuperscript{44} MRI has become routinely available outside the medical field in recent years. Materials analysis, particularly studies of fluids in porous materials and fluid diffusion into bulk materials, has been a major area of interest.\textsuperscript{44} While the majority of MRI is still of mobile $^1\text{H}$ nuclei, imaging of other nuclei and of solids is expanding rapidly, offering even more powerful methods for the NMR analysis of geological and glassy materials.
The basic imaging experiment relies on a linear magnetic field gradient to introduce position-dependent frequency shifts enabling signals from different parts of the sample to be distinguished. Gradients can then be varied in the x, y and z directions to produce 3-D images. Spin–lattice relaxation ($T_1$) maps are commonly used for water and other mobile fluids. The spatial resolution is limited in practice to a few micrometers in liquids and an order of magnitude larger in solids, because of line width, signal-to-noise ratio and diffusion effects.

Contrast techniques for solid-state imaging enable a much wider range of inorganic materials to be investigated. Imaging in solids is inherently more difficult owing to dipole–dipole and chemical shift interactions leading to large line widths and low signal-to-noise ratios. The lower sensitivity ultimately limits the resolution which can be obtained. This problem can be reduced by a range of strategies including the use of larger magnetic field gradients and by line-narrowing techniques. Multiple-pulse methods used to obtain high resolution in conventional NMR spectra of solids have been incorporated into imaging from its early development. A large range of line-narrowing methods is now in use, including MAS and magic angle in the rotating frame and multiple pulse techniques such as CRAMPS.\(^{44}\)

Conventional MRI techniques are eventually limited by the rate of spin–spin relaxation though continuing developments in probe technology as well as pulse sequences are extending its capabilities to systems with shorter $T_2$ values. The complementary approach of stray field imaging (STRAFI) extends the applications of imaging in solids even further.\(^{45–47}\) STRAFI makes use of the very large gradients in the fringe field of superconducting magnets. The RF pulse excites a narrow slice of the sample orthogonal to the gradient direction. The sample is then moved through the gradient and a series of slices is measured using echo detection, giving a 1-D profile. Rotation of the sample can be used to give 2-D or 3-D images. However 3-D imaging using STRAFI is still technically difficult since it requires precise translation and rotation of the sample, with reconstruction of the image from individual slices by back-projection. STRAFI is successful for signals over a very wide range of $T_2$ values including very broad signals. Apart from $^1$H, its application to a number of other nuclei of importance in inorganic materials has been demonstrated\(^{45–47}\), including $^{19}$F, $^{11}$B, $^{23}$Na, $^{27}$Al and $^7$Li.

Finally, another development of importance to the imaging inorganic solids by NMR should be mentioned. This is NMR force microscopy\(^{148,49}\), which has the potential to achieve higher spatial resolution in solids than conventional imaging.

### 3 APPLICATIONS

#### 3.1 Speciation and Structure Determination

Tables 4–10 summarize the applications of NMR to speciation and structure determination in glasses, gels, ceramics and minerals. The examples in the tables are organized according to the nucleus studied. In the following sections we discuss selected applications to the different classes of materials.

##### 3.1.1 Silicate and Aluminosilicate Glasses

$^{29}$Si NMR has been extensively applied to these systems for many years, and the subject has been comprehensively reviewed on several occasions.\(^{1,50–52}\) The isotropic chemical shift for a $^{29}$Si atom depends on both its chemical environment and on the local geometry; $^{29}$Si spectra can thus provide information about both aspects of glass structure.

For tetrahedrally coordinated silicon, the chemical shift depends on the number of bridging oxygen atoms attached to the silicon. The standard terminology used is to identify the silicon sites as Q1, Q2, Q3 or Q4, where the subscript refers to the number of bridging oxygens connected to other tetrahedral sites. For Q1, Q2 and Q3 silicons, the remaining coordination sites are occupied by hydroxyl groups. Approximate chemical shift ranges for each type of silicon are as follows (relative to tetramethylsilane):\(^{52}\)

<table>
<thead>
<tr>
<th>Si species</th>
<th>Chemical shift (ppm)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Q4 (0Al) $^{29}$Si(OSi)$_4$</td>
<td>$-(100–116)$ ppm</td>
</tr>
<tr>
<td>Q4 (1Al) $^{29}$Si(OSi)$_3$OAl</td>
<td>$-(100–116)$ ppm</td>
</tr>
<tr>
<td>Q4 (2Al) $^{29}$Si(OSi)$_2$(OAl)$_2$</td>
<td>$-(92–102)$ ppm</td>

<td>$-(88–96)$ ppm</td>
</tr>
<tr>
<td>Q4 (4Al) $^{29}$Si(OAl)$_4$</td>
<td>$-(80–90)$ ppm</td>
</tr>
</tbody>
</table>

A second influence on the $^{29}$Si chemical shift is the substitution of silicon by other tetrahedral elements, particularly aluminum. The chemical shift becomes less negative with increasing replacement of adjacent silicon by aluminum, thus:

</table>

Speciation of silicon in a silicate or aluminosilicate requires resolution of the different components in the spectrum. In the case of glasses, the lines are relatively broad, and curve-fitting techniques must be employed. Mahler and Sebald\(^{53}\) have given a critique of the assumptions used in line shape fitting. Most authors have assumed a Gaussian line shape function, but Mahler and Sebald showed by means of selected examples that it
may not be possible to obtain a single unique solution to the problem of fitting a $^{29}$Si NMR spectrum with several components. Notwithstanding this cautionary conclusion, curve fitting is still used to obtain at least semiquantitative distributions of silicon species. For example, Fayon et al.\cite{54} examined a series of lead silicate glasses of varying lead contents. In this case the observed $^{29}$Si spectra contain up to five components which are assigned to silicon atoms bonded through oxygen to four, three, two, one or no neighboring silicon atoms. Figure 9 shows the distribution obtained.

At high lead contents, the dominant silicon species are those bridged to two, one or no Si atoms, corresponding to $\text{Si}_3\text{O}_{10}^6$, $\text{Si}_2\text{O}_7^4$ and $\text{SiO}_4^4$ anions respectively. Comparison with $^{207}$Pb NMR spectra for the same series of samples leads to the conclusion that the lead content is increased the silicate network is destroyed and replaced by a polymeric lead oxide chain structure.

The sensitivity of the $^{29}$Si chemical shift to the number of aluminum next-nearest neighbors in aluminosilicate glasses has been used recently by Lee and Stebbins\cite{55} to investigate the degree of aluminum avoidance in such materials. The often-cited Loewenstein’s rule postulates that the $\text{Si}–\text{O}–\text{Al}$ linkage is more favorable than the alternative $\text{Si}–\text{O}–\text{Si}$ and $\text{Al}–\text{O}–\text{Al}$ combination. In crystalline aluminosilicates, Loewenstein’s rule seems to be well established, but in the case of glasses the extent to which it is followed is still an open question. This is largely due to the difficulties of resolving the signals due to different $\text{Si(OAl)}_n$ species in glass samples. The approach taken by Lee and Stebbins was to fit the broad asymmetric single peaks with up to five Gaussian peaks corresponding to the five possible $\text{Q}_4$ Si species with 0–4 Al next-nearest neighbors. A speciation model was used in which the relative proportion of $\text{Al}–\text{O}–\text{Si}$, $\text{Si}–\text{O}–\text{Si}$ and $\text{Al}–\text{O}–\text{Al}$ linkages were calculated as a function of glass composition, assuming the quasi-chemical approximation (which assumes the number of each species depends on their relative energy differences). Spectra were then fitted with different possible values of the aluminum

Avoidance parameter $Q$ ($Q = 0$ represents a totally random distribution of Si and Al, taking no account of Loewenstein’s rule, and $Q = 1$ perfect compliance with Loewenstein’s rule).

For calcium aluminosilicate glasses, the observed spectra could be fitted over the complete compositional range with values of $Q$ between 0.8 and 0.875. For sodium aluminosilicate glasses, on the other hand, values of $Q$ closer to 1.0 (0.93–0.99) were obtained. In both types of glass there is clearly a very substantial degree of aluminum ordering present, representing the structure of the liquid at the glass transition temperature.
The low resolution in $^{29}$Si NMR spectra of glasses is due to the presence of a distribution of Si–O–Si bond angles. Theoretical calculations indicate a spread of as much as 40° around a mean of ca. 145°.\(^{53}\) Correlations of chemical shift with bond angle are well established in the crystalline silicate and aluminosilicate literature, and supported by quantum mechanical calculations.\(^{56}\) The possibility of obtaining experimental evidence for Si–O–Si bond angle distributions from $^{29}$Si NMR spectra might therefore be considered. In practice, however,

Figure 9 Distribution of $Q_n$ silicon sites as a function of PbO content in lead silicate glasses. [Reproduced with permission from Fayon et al.54]

the uncertainties associated with curve fitting and the difficulty of separating structural from chemical influences on chemical shift preclude any reliable conclusions being drawn. As discussed below, $^{17}\text{O}$ NMR, which observes the bridging oxygen atoms directly, may offer more hope of studying bond angle distributions.

$^{29}\text{Si}$ NMR spectroscopy can easily distinguish five- and six-coordinate Si in glasses containing these unusual species. Octahedrally coordinated Si has chemical shifts between $-180$ and $-221$ ppm, while pentacoordinated Si has been detected in small concentrations in certain cesium and sodium silicate glasses at a chemical shift of about $-150$ ppm.

As noted in section 2.2.6 (and discussed further below), 2-D correlation $^{29}\text{Si}$ NMR spectroscopy has proved to be a powerful tool for studying connectivity of Si atoms.
in crystalline silicates and aluminosilicates, particularly zeolites. Knight et al.\textsuperscript{(59)} first described a ²⁹Si COSY experiment on silicate glasses which had been isotopically enriched with ²⁹Si. They showed the first direct evidence that O₃ and Q₄ Si sites in sodium silicate glasses were connected; the intensities of the cross peaks in the 2-D COSY spectra arising from ²⁹Si–²⁹Si dipolar coupling decreased as the level of ²⁹Si enrichment was lowered.

More recently, an alternative approach for measuring Si connectivity has been described by Glock et al.\textsuperscript{(60)} This uses the 2-D double quantum NMR experiment first described by Fieke et al.\textsuperscript{(61)} In this experiment, only dipolar coupled ²⁹Si nuclei are detected (isotopic enrichment was used to enhance sensitivity). Peaks due to double quantum coherences between chemically identical spins appear on the diagonal of the 2-D spectrum, and off-diagonal peaks are due to double quantum coherences between chemically different sites. For a ²⁹Si-enriched sodium silicate glass, Glock et al. identified three different Q₃ Si sites at about −89, −92 and −95 ppm, assigned to O₃ silicon atoms connected to 3O₃ silicons, 2Q₃ and 1Q₄ silicons and 1Q₃ and 2Q₄ silicons respectively. Likewise, the three different Q₄ sites resolved at about −102, −105 and −108 ppm were assigned to Q₄ silicon atoms connected to different numbers of O₃ and Q₄ silicons. The power of this technique to identify connectivities at a level of resolution impossible in conventional one-pulse MAS NMR spectra offers many possibilities for the study of silicate glasses (the authors have also used this method to study phosphate glasses, as described below).

²⁷Al NMR spectroscopy has provided many insights into the structure and speciation of aluminosilicate glasses. The effects of quadrupolar broadening were described in section 2.8. In glasses, the additional broadening caused by structural disorder makes analysis of conventional one-pulse MAS ²⁷Al NMR spectra difficult. The presence of four-, five- and six-coordinate aluminum (chemical shifts at −10 to 15, 35 to 40 and 50 to 80 ppm, respectively, in aluminosilicates) can often be qualitatively determined by curve fitting asymmetric line shapes. Several of the newer NMR techniques for enhancing ²⁷Al resolution and extracting structural information from quadrupole parameters have been successfully applied to glass systems.

For example, Dirken et al.\textsuperscript{(62)} used the off-resonance nutation technique to determine the quadrupole parameters for ²⁷Al in alkali metal aluminosilicate glasses. The conventional MAS spectra of these samples show a single broad peak at the chemical shift expected for tetrahedrally coordinated aluminum, with a line width which decreases with increasing size of the alkali metal cation. The contributions to the line width from a distribution of chemical shifts and from second-order quadrupolar broadening cannot be easily separated, however (unless spectra are recorded at several different field strengths). As described in section 2.9, nutation is a 2-D experiment in which the f₁ dimension contains the nutation spectrum, which is a sensitive function of the quadrupole parameters only. By comparing the observed nutation spectra with those computed when different possible quadrupole parameters, the mean coupling constants and asymmetry parameters could be obtained.

The mean coupling constants in this series of glasses were found to correlate linearly with the polarizing power of the alkali metal cation, suggesting that the quadrupole interaction is dominated by the perturbation of electron density around Al by a nearby alkali metal ion. The values of the quadrupole parameters obtained from the nutation spectra were then used to calculate the conventional MAS line shapes and deduce the isotropic chemical shift and chemical shift dispersion. The isotropic chemical shifts were found to decrease with increasing size of the cation, which may indicate changes in the Al–O–Si bond angle,\textsuperscript{(63)} but the chemical shift dispersion (reflecting the degree of structural disorder) remained approximately constant. The authors concluded that ²⁷Al NMR of these systems is much more structurally informative than ²⁹Si NMR.

An alternative approach which has been applied with some success to ²⁷Al in disordered systems is satellite transition spectroscopy. As noted above, the central (½ ↔ −½) transition for a nonintegral quadrupolar nucleus is broadened owing to second-order quadrupolar interactions and to chemical shift dispersion. The satellite transitions (e.g. ½ ↔ ½) show higher resolution, however, which can allow the isotropic chemical shift and quadrupole coupling constants to be obtained with a greater degree of confidence. For example, Figure 10(a–f) compares the conventional (central transition) MAS spectra of several potassium aluminosilicate glasses with differing potassium contents with the corresponding satellite transition spectra.\textsuperscript{(64)} The signals due to tetrahedral and octahedral Al are clearly much better resolved in the satellite transition spectra, and can be readily quantified. Furthermore, in two of the samples there is partial resolution of two different tetrahedral sites with slightly different isotropic chemical shifts. The quadrupole coupling constants calculated from the spinning side band patterns decreased on adding potassium.

Direct structural information about silicate and aluminosilicate glasses is obtained from observation of ¹⁷O NMR spectra. The Si, Al ordering in such glasses can be investigated since the ¹⁷O quadrupolar coupling constants are significantly different for Si–O–Si, Si–O–Al and Al–O–Al linkages. An example from Dirken et al.\textsuperscript{(29)} was shown in Figure 6. In this particular example of an albite glass, the conventional single quantum ¹⁷O MAS spectrum shows two overlapping signals which cannot
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 10 (a–c) Central and (d–f) satellite transition $^{27}$Al spectra of potassium aluminosilicate glasses with different K : Al ratios. be quantified. The triple quantum spectrum (Figure 6) clearly separates two signals which can be assigned to Si–O–Si and Si–O–Al bridging oxygens; the single quantum spectrum can then be fitted with the sum of these two contributing signals to obtain a reliable estimate of the relative numbers of the two types of bridging oxygen.

Related studies of oxygen speciation have been reported by Stebbins et al.65–67 For example, in mixed barium–calcium silicate glasses the MQMAS experiment separates bridging (Si–O–Si) from terminal (Si–O) oxygen atoms. The terminal Si–O oxygen projections on the isotropic chemical shift axis for the mixed glasses could be fitted assuming a random distribution of Ba and Ca on the three cation sites adjoining each terminal oxygen, i.e. there is no evidence for cation ordering in these particular materials.65 In a calcium aluminosilicate glass, the $^{17}$O MQMAS experiment finds direct evidence for Al–O–Al linkages in violation of Loewenstein’s rule,66 whereas in hydrous silicate glasses at least four different oxygen species have been detected (Si–O–Si, Si–O, Si–OH and H$_2$O).67

NMR spectroscopy has also been applied to study the cations in silicate and aluminosilicate glasses and also the framework elements. Table 10 lists some of the NMR-visible nuclei which have been studied in this way. In the case of protons, Schaller and Sebald68 applied the CRAMPS technique to observe OH and H$_2$O species in hydrous silicate glasses. The line widths of the two signals at about 12 and 4 ppm were unchanged, however, between the CRAMPS experiment, in which dipolar decoupling is applied, and the conventional MAS experiment, indicating that the line width is mainly due to chemical shift dispersion. The presence of dipolar coupling between the OH and H$_2$O sites was shown by the observation of cross peaks in a 2-D spin exchange spectroscopy (EXSY) experiment. Schaller and Sebald also showed that the spinning side band patterns associated with the two kinds of proton sites could be separated by carrying out a 2-D CRAMPS/MAS correlation experiment in which the $f_2$ axis is the MAS spectrum and the $f_1$ axis is the CRAMPS spectrum. Figure 11 shows the resulting 2-D spectrum; the spinning side band pattern for each of the two sites can
then in principle be analyzed to obtain dipolar coupling constants.

The local environment and spatial distribution of alkali metal ions in silicate and aluminosilicate glasses has been studied by $^{23}$Na, $^7$Li and $^6$Li NMR. For $^{23}$Na and $^7$Li the line widths in conventional MAS NMR spectra are dominated by quadrupolar effects, and direct chemical information is difficult to obtain. Nevertheless, Ali et al.\(^{69}\) were able to show for a series of mixed sodium–lithium silicate glasses that the apparent $^{23}$Na and $^7$Li chemical shifts and line widths varied continuously across the composition range, concluding that the two cations were randomly mixed with no ordering occurring. In the case of $^6$Li, the quadrupole moment is sufficiently small that the observed center of gravity in a MAS spectrum is very close to the isotropic chemical shift, i.e. this nucleus behaves effectively as though it were spin $^1/2$. $^6$Li chemical shifts in a range of different crystalline environments have been established; there is an approximately linear correlation between $^6$Li chemical shift and coordination number (e.g. from 1.5 ppm relative to aqueous LiCl for three-coordinate Li to $-1.5$ ppm for eight-coordinate Li).\(^{70}\) In a lithium silicate glass, the $^6$Li spectrum showed a broad peak indicating a distribution of coordination numbers between 4 and 6.

Gee and Eckert\(^{71}\) used $^{23}$Na spin echo decay spectroscopy to measure $^{23}$Na–$^{23}$Na dipole–dipole couplings in sodium silicate glasses. Spin echo decay spectroscopy measures the intensity of a spin echo as a function of the evolution time; in these systems the mechanism responsible for spin echo decay is assumed to be dipolar coupling. The observed decay can be fitted to obtain a $^{23}$Na–$^{23}$Na second moment, which contains the dipolar coupling. The resulting second moments, when plotted against the sodium content of the glass, best fitted a model of homogeneous distribution of sodium cations rather than a random distribution.

The double resonance techniques of REDOR and SEDOR have been applied to investigate the $^{23}$Na/$^7$Li or $^{23}$Na/$^6$Li distributions in mixed sodium–lithium silicate glasses,\(^{72–74}\) but in these materials the data could be best fitted by assuming a random distribution of the two cations.

The investigation of lead silicate glasses by $^{29}$Si NMR was described above. The $^{207}$Pb signals from these materials are broad and poorly defined, reflecting the large chemical shift range shown by $^{207}$Pb. Nevertheless, as shown in Figure 12, there is a definite evolution in line shape and position as the lead content of the glasses changes.

Up to 50 mol% PbO the isotropic chemical shift remains constant, at a value consistent with chains of distorted PbO$_4$ pyramids; at higher loadings the increasing chemical shift was interpreted in terms of formation of Pb–O–Pb units.

### 3.1.2 Germanate and Borate Glasses

Germanium dioxide shows many structural similarities to silica, and can form similar glassy structures. Hussin et al.\(^{75}\) recently reported an $^{17}$O NMR investigation of a GeO$_2$ glass to determine the Ge–O–Ge bond angle distribution. Samples were enriched in $^{17}$O to enhance sensitivity, and spectra were collected in static and MAS modes. The spectra (both static and MAS) of the glass differed from those of the crystalline quartz-like GeO$_2$ only in line width. The glass line shapes were fitted with a model assuming a Gaussian distribution of Ge–O–Ge bond angles; it was concluded that the distribution is fairly

---

**Figure 12** $^{207}$Pb static spectra of lead silicate glasses. [Reproduced with permission from Fayon et al.\(^{54}\)]
narrow, around a mean of 130° with a half-width of no more than 4°.

In the case of borate or borosilicate glasses, 11B NMR can provide useful structural information. The relative concentrations of three- and four-coordinate boron can easily be determined from static and MAS spectra, and the DAS technique has been applied to enhance resolution. As in the case of aluminum, resolution enhancement can also be achieved using 11B satellite transition spectroscopy. Jäger et al. examined a series of sodium borosilicate glasses with this technique, and identified two different BO4 sites and three different BO3 sites.

Double resonance 11B–27Al and 27Al–11B experiments on sodium aluminoborate glasses have been reported by Van Wuellen et al. The single-pulse 11B MAS spectra of these glasses show two overlapping signals due to three- and four-coordinate boron. Application of 27Al CP enhances only the three-coordinate boron signal, showing unambiguously the connectivity of BO3 and AlO4 sites. Likewise, a 11B (27Al) REDOR experiment showed that there is a much larger dipolar coupling between 27Al and the three-coordinate boron than the four-coordinate boron.

In borosilicate glasses, the assumption is generally made that three-coordinate boron does not mix with the silica network. Wang and Stebbins have recently shown by triple quantum magic angle spinning (3QMAS) 17O NMR that this assumption is not correct. Figure 13 shows the triple quantum spectrum of a 17O enriched borosilicate glass containing 40 mol% B2O3.

The enhanced resolution of the MQMAS experiment allows the presence of three different bridging oxygen species to be resolved. In particular, there is a large contribution to the spectrum from Si−O−B species, implying that three-coordinate boron is incorporated into the silica network.

### 3.1.3 Phosphate Glasses

Kirkpatrick and Brow reviewed in 1995 the use of NMR to characterize phosphate and phosphate-containing glasses. 31P, as a spin = 1/2 nucleus, gives MAS spectra in which the isotropic chemical shift is a sensitive function of the coordination environment and geometry. For example, the degree of polymerization of tetrahedral phosphate units is easily determined from the chemical shift, and the effects of other elements on the phosphate polymerization and the formation of P−O−X units has been widely studied. Losso and Sternberg examined the 31P chemical shift tensor components and the distribution of values existing in glasses using static and MAS measurements.

The connectivity between different phosphate units in sodium, calcium phosphate glasses has been investigated by 2-D exchange NMR. The 1-D MAS spectra of these materials show two signals due to phosphorus connected through oxygen to one and two neighboring phosphorus, respectively (so-called Q1 and Q2). In the 2-D spectra, cross peaks are observed due to dipolar coupling between Q1 and Q2 sites, showing that these sites are connected.

Connectivity between phosphorus and aluminum or sodium in phosphorus-containing aluminosilicate glasses has been investigated by Schaller et al. using the double resonance TRAPDOR technique. The 31P MAS spectra of these samples show up to five different signals. The TRAPDOR measurements allow these to be assigned to phosphorus sites linked to different numbers of Na and/or Al cations.

### 3.1.4 Fluoride-containing Glasses

19F as a highly abundant spin = 1/2 nucleus can provide much useful information about fluoride-containing glasses. The chemical shift range for fluorne-containing compounds covers more than 200 ppm. As an example, Figure 14 shows the 19F MAS spectrum of a PZG (PbF2−ZnF2−GaF3) glass reported by Bureau et al. The spectrum is broad because of dipolar coupling not removed by MAS, and contains spinning side bands. Nevertheless, the spectrum could be fitted as the sum of the three components shown, at around 10, 65 and 156 ppm (relative to C6F6).

From comparisons with fluoride compounds of known structure, the authors assigned the three signals to free fluoride ions, fluoride ions in MF6 octahedra.
and fluoride ions bridging between MF₆ octahedra, respectively, and they were able to follow the relative concentrations of these species as a function of glass composition.

3.1.5 Gels

The speciation of silicon in gels and gel precursors by ²⁹Si NMR follows very closely that in glasses: the chemical shift is a sensitive function of the silicon coordination and local structure. For example, Pauthe et al.\(^{[86]}\) prepared silicon nanocrystallites embedded in a silica matrix by a sol–gel route using triethoxysilane as the precursor. ²⁹Si NMR spectra were measured after firing the gels at temperatures from 100 to 1000 °C, and showed the gradual loss of monomeric HSiO₃ units and the appearance of the Q₃ and Q₄ signals characteristic of bulk silica gel. At high temperatures, a signal assigned to crystalline silicon at −81 ppm appeared.

²⁹Si NMR has also been used in the characterization of hybrid gel materials prepared from polydimethylsiloxane precursors. In this case, retention of the linear dimethylsiloxane backbone was confirmed from the spectrum.\(^{[87]}\)

²⁷Al NMR is likewise used to characterize precursors and intermediate phases in the formation of alumina or composite alumina-containing gels. Figure 15 shows, for example, ²⁷Al MAS NMR spectra of aluminosilicate gels as a function of firing temperature, reported by Peeters and Kentgens.\(^{[88]}\)

The initially formed gel shows two well resolved peaks associated with tetrahedral and octahedral aluminum, respectively, but after firing the spectrum broadens in a complex manner. In order to enhance the resolution, Peeters and Kentgens performed 3QMAS measurements on the same samples. Figure 16 shows the 3QMAS spectrum of the gel heated to 200 °C, in which the signals of the three different aluminum species can be clearly resolved and quantified.

![Figure 14](image1.png)

**Figure 14** ¹⁹F NMR spectrum of a PZG glass. [Reproduced with permission from Bureau et al.\(^{[85]}\)]

![Figure 15](image2.png)

**Figure 15** ²⁷Al MAS spectra of aluminosilicate gels after heating for 2 h at each of the temperatures indicated. [Reproduced with permission from Peeters and Kentgens.\(^{[88]}\)]

![Figure 16](image3.png)

**Figure 16** ²⁷Al 3QMAS spectrum of aluminosilicate gel fired to 200 °C. The deviations from the diagonal axis reflect a distribution of quadrupole parameters. [Reproduced with permission from Peeters and Kentgens.\(^{[88]}\)]
The quadrupole coupling parameters and distribution were estimated from comparisons of the observed spectra with calculated spectra, and the values obtained were corroborated by off-resonance nutation measurements.

A similar approach was taken by Soraru et al., who used $^{11}$B 3QMAS NMR to resolve different boron sites in organically modified borosilicate gels. In particular, a high concentration of $^{11}$B/$^{28}$Si bonds was detected by this technique.

$^{17}$O NMR is a powerful technique for characterizing both gels and glasses. For example, $^{17}$O MAS NMR was used by Dirken et al. to distinguish between Ti–$^{28}$Si and Ti–$^{18}$O bonds in titanosilicate gels.

### 3.1.6 Gel Precursors

Oxide glasses and hybrid organic–inorganic glassy materials can be synthesized by low-temperature hydrolysis and condensation of soluble precursors, usually alkoxides. Thus silicates are produced from alkoxysilanes, principally TEOS and tetramethoxysilane (TMOS). The initially formed hydrated gels can be further processed by dehydration and thermal treatment to form dense glasses. Not surprisingly, NMR spectroscopy finds an important role in the characterization of the resulting materials as discussed in section 3.1.5. There is a vast literature covering this area, a detailed review of which is not attempted here. Therefore, this section will cover the reactions leading to the formation of gels and the applications of NMR in characterizing the intermediates (see Table 11).

Multinuclear magnetic resonance spectroscopy has become an important technique in sol–gel chemistry where the hydrolysis and condensation reactions leading to gel formation can be monitored. High-resolution solution-state spectroscopic techniques are applicable prior to gel formation and provide structural, kinetic and mechanistic data. $^{29}$Si NMR is used to monitor the Si species formed during reactions of alkoxysilanes. Figure 17 shows the $^{29}$Si chemical shift assignments for silicon sites in TEOS sol–gel systems.

The $^{29}$Si NMR spectrum of sol–gel systems can be observed past the gelation point, under solution-state conditions, indicating that the mobility of the oligomers remains. The transition from sol to gel has been monitored in situ by $^1$H spin–spin relaxation measurements. Gelation of water-glass silicate solutions was accompanied by a decrease in $T_2$ of the water protons to a minimum value. Subsequent aging of the gels was associated with a

*PGSE, pulsed gradient spin echo; MTES, methyltriethoxysilane.*
the difficulties with $^{29}$Si NMR, the relative insensitivity and DEPT have been employed to overcome two of the difficulties with $^{29}$Si NMR, the assignment of Si sites according to the number of attached hydroxy groups. Figure 18 shows the $^{29}$Si DEPT spectrum of a MTES reaction mixture at pH 2.4, in which the various silicon monomers and oligomers are resolved. The $T^n$ notation refers to the number of siloxane bonds so that $T^0$ are monomers, $T^1$ end groups of chains and $T^2$ central sites in chains or rings.

$^{17}$O enrichment is easily achieved in sol–gel systems and $^{17}$O NMR has found increasing application in this field both to follow the fate of water during the early stages of reaction$^{(97)}$ and using MAS spectroscopy to detect different oxygen coordination modes in gels and oxide products.

### 3.1.7 Minerals

The speciation of silicon in silicate minerals by $^{29}$Si NMR follows that in other materials; the higher resolution achieved in crystalline mineral phases means that $Q_4$ and $Q_3$ species with different next-nearest neighbors can be more reliably identified and quantified than in silicate glasses, for example.$^{(98)}$ Kohn et al. have identified up to 10 distinct Si sites in various synthetic leucite analogs.$^{(99)}$

The use of 2-D chemical shift correlation spectroscopy to establish connectivity between different silicon sites in crystalline synthetic zeolites by Fyfe et al.$^{(15)}$ was referred to in section 2.6. $^{29}$Si MAS and CPMAS have been used to characterize the phases present in microcrystalline opals.$^{(100)}$ $^1$H CP was used to show the presence of large concentrations of internal SiOH groups in these materials.

$^{29}$Si NMR has been used also to follow the process of dealumination of kaolinite clays with hydrochloric acid treatment.$^{(101)}$ In this case, the conversion of Si–O–Al species to Si–O–Si species with reaction time could be quantitatively monitored and a mechanistic model proposed.

The problem of quantifying and speciating aluminum in crystalline minerals, particularly in terms of eliminating quadrupolar broadening, has been addressed by several groups recently. Alemany et al. have undertaken very fast $^{27}$Al MAS measurements on kyanite and andalusite at three different magnetic field strengths (9.4, 11.65 and 18.8 T), and compared the spectra obtained with the corresponding 3QMAS spectra.$^{(21)}$ Figure 19 shows 1-D MAS and 2-D 3QMAS spectra of kyanite, measured at 9.4 T and a MAS rate of 22 kHz.

Kyanite contains four different octahedral Al sites, and in the 1-D MAS spectrum these cannot be separated, regardless of the magnetic field strength used. The three signals clearly resolved in the 3QMAS spectrum have an intensity ratio of 2 : 1 : 1, indicating that two of the Al sites have the same apparent isotropic chemical
shift at this field. From measurements of the MAS and 3QMAS spectra at three different magnetic fields, however, Alemany et al. were able to calculate accurately the quadrupole coupling constants and true isotropic chemical shifts for the four sites.

A useful comparison of the different techniques for obtaining $^{17}$O NMR spectra [static, MAS, variable-angle spinning (VAS), DAS and MQMAS] of the zeolite mineral stilbite has been reported by Xu and Stebbins.\textsuperscript{102} Figure 20(a–d) summarizes the spectra obtained.

The static spectrum clearly shows two overlapping quadrupolar powder patterns, with a total width of ca. 400 ppm at 9.4 T. This is narrowed to ca. 80 ppm in the isotropic dimension. The improved resolution is due to the removal of anisotropic second-order quadrupolar broadening by the DAS experiment, and the remaining line widths of ca. 20 ppm are due at least in part to a distribution of isotropic chemical shifts in the sample. The distribution of quadrupole parameters for the two sites was investigated by simulating VAS slices across the 2-D DAS spectrum. In the 3QMAS spectrum, chemical shift anisotropy and dipolar interactions are eliminated to first order, and the two oxygen sites are now clearly resolved with line widths of <10 ppm in the isotropic dimension. The quadrupole parameters obtained by simulating the different spectra (static, DAS and 3QMAS) agree moderately well; Xu and Stebbins argued that the 3QMAS-derived quadrupole data are the most reliable.

The 3QMAS technique has also been applied to $^{23}$Na NMR of sodium cations in various zeolites by Hunger et al.\textsuperscript{103} In these systems, the presence of Na\textsuperscript{+} in one or more cation-exchange sites is evident from the occurrence of partially resolved shoulders on the 1-D MAS spectra, but the distinction between a second-order quadrupolar powder pattern and multiple overlapping isotropic chemical shifts cannot easily be made. The 3QMAS experiment allows this separation to be done; Hunger et al. reported isotropic chemical shifts and quadrupole coupling constants for Na\textsuperscript{+} in the different exchange sites identified.

$^{113}$Cd NMR has been used by Sullivan et al.\textsuperscript{104} to investigate cation binding in montmorillonite clays. In particular, they undertook double resonance SEDOR experiments to investigate the coupling between $^{113}$Cd and $^{27}$Al in order to study cation sites in the clay. In the case of hydrated clays, no coupling was observed, owing to rapid motion of hydrated cations within the clay layers. For freeze-dried samples, however, significant SEDOR intensity reduction was observed, indicating strong dipolar coupling between $^{113}$Cd and $^{27}$Al cations in the octahedral sheets of the montmorillonite structure. Since the distance between such aluminum ions and the interlayer space of the clay is > 5 Å (the largest distance over which dipolar coupling is operative), it was concluded that in the dried clay the Cd cations move to pseudo-hexagonal holes in the tetrahedral sheets.

3.1.8 Ceramics

NMR has found many applications in studying the formation and crystallization of ceramic phases prepared from sol–gel and glass precursors. For example, $^{23}$Na, $^{27}$Al and $^{31}$P NMR have been used by Abrahams et al. to characterize bioactive ceramics prepared from CaO–Na\textsubscript{2}O–P\textsubscript{2}O\textsubscript{5}–Al\textsubscript{2}O\textsubscript{3} glasses.\textsuperscript{105} $^{23}$Na MAS spectra from such materials are broad and poorly resolved, but suggest the possibility of two different Na\textsuperscript{+} sites. By applying 3QMAS NMR, these two species could be clearly separated, and their quadrupole coupling parameters determined. The reliability of the analysis was checked by successfully simulating the single-quantum MAS spectra with the parameters obtained. The corresponding $^{31}$P MAS spectra showed two principal bands assigned to Q\textsubscript{1} and Q\textsubscript{2} phosphate units. From a Herzfeld–Berger analysis\textsuperscript{106} of the spinning side band intensities in these spectra, the chemical shift tensor components of these two species were obtained, confirming the assignment.
Changes in the speciation of oxygen during the formation of La₂O₃ from various precursors was followed by Ali et al.¹⁰⁶ using ¹⁷O MAS NMR on enriched materials. The formation of the oxide was shown to occur via an intermediate LaO(OH) species not previously observed in other oxide gels.

Brieger et al.¹⁰⁷ used ²⁰⁷Pb NMR to follow the pyrolysis and crystallization of lead zirconate titanate ceramics prepared by sol–gel methods. The parent gels show broad, unresolved ²⁰⁷Pb MAS spectra; the absence of resolved spinning side bands was attributed to the superposition of signals from lead species in a distribution of different environments. Upon crystallization, the signals narrow and spinning side bands are resolved. The line widths of the resulting signals were strongly influenced, however, by the particular preparation method used, indicating that there can be wide variations in local order within ceramics showing identical crystallinity by X-ray diffraction.

The use of ⁶Li and ⁷Li MAS NMR to aid in the nondestructive analysis of lithium aluminate ceramic phases has been reported by Stewart et al.¹⁰⁸ ⁶Li was found to give a single, narrow resonance with no spinning side bands, suggesting that a single lithium site is occupied, and the intensity of the signal was found to be directly proportional to the concentration of lithium in the sample, provided that enough time was allowed for spin–lattice relaxation. ⁷Li gave a much more intense signal than ⁶Li, with spinning side bands resulting from the larger quadrupolar interactions expected for this nucleus. The static spectrum was also measured to obtain the quadrupole coupling constant.

3.1.9 High-temperature Glasses, Liquids and Melts

The use of NMR to investigate the structure and dynamics of oxide melts is aimed at understanding both geological and synthetic glassy materials. Magmas and
lava cannot be studied directly by NMR but laboratory experiments can provide insights into the properties of these molten systems through model studies of oxide melts and supercooled liquids over an increasingly wide range of temperatures and pressures. Spectroscopic analysis of glasses formed by quenching of melts at different rates and of the melts themselves provides fundamental information on the structure of the liquid phase. Investigation of glass structure and dynamics at the glass transition temperature \((T_g)\) and above provides information on slower exchange processes which are completely averaged out in the melt. This area has been reviewed in detail in 1991 and 1995\(^3\)\(^3\) and NMR spectroscopy has also been evaluated in comparison with vibrational spectroscopy for the analysis and characterization of melts.\(^1\)\(^0\)

The onset of molecular motion above \(T_g\) results in exchange of Si between coordination sites with complete averaging and narrow line widths in the melt. Figure 21(a–f) shows the \(^{29}\)Si NMR spectrum of K\(_2\)Si\(_4\)O\(_9\) as a function of temperature from 697 to 997 °C. The increasing rate of chemical exchange between Q\(_3\) and Q\(^2\) sites was determined by simulation of the peak shapes.

Similar line narrowing is observed for nonframework nuclei such as Li, Na and Mg. Static \(^{25}\)Mg spectra for a magnesium aluminosilicate were only observed above 1000 °C and showed significant line narrowing on further heating from 1200 to 1440 °C.\(^1\)\(^0\) High-temperature 2-D exchange spectra are sensitive to processes on a timescale of seconds. Such experiments have been carried out on liquids just above \(T_g\), enabling exchange to be detected at frequencies less than the peak width. This is illustrated by the spectra for K\(_2\)Si\(_4\)O\(_9\) above \(T_g\) at 555 °C (Figure 22a and b), which show off-diagonal peaks at longer mixing times, indicative of substantial exchange between Q\(_3\) and Q\(^4\) silicon sites.

Fast exchange in high-temperature melts means that structural details of Si coordination in the liquid are averaged out, as seen above. There are two strategies to recover this information. One is to quench the melt at different rates, thus freezing in changes in liquid structure at a fictive temperature \(T_f\). This strategy has been used to identify Si(V) and Si(VI) coordination sites which are found to increase in importance at higher temperatures in the melt. Similarly, in aluminosilicates, Al(V) and Al(VI) coordination has been observed in glasses quenched at high \(T_f\) and high pressure.\(^1\)\(^1\) Oxygen site exchange accompanies averaging of Si, Al or B sites in oxide melts and hence \(^{17}\)O NMR has also been used to identify changes in bridging and nonbridging oxygen sites in quenched glasses.\(^1\)\(^2\) In cases where the liquid can be supercooled, exchange is slowed and coordination information can be obtained in the liquid state.\(^1\)\(^3\)

Relaxation measurements are sensitive to motion on a timescale of nanoseconds. On heating a silicate glass above \(T_g\), the temperature dependence of the spin–lattice relaxation time, \(T_1\), shows a discontinuity associated with the onset of long-range motion in the glass.\(^1\)\(^1\) Non-framework nuclei do not show the same effect. Apparent activation energies can be extracted from Arrhenius plots of relaxation data both above and below the \(T_1\) minimum. However, in both glasses and melts, these values are generally not the same, with a higher \(E_a\) found on the high-temperature side of the minimum. This has been attributed to the dominance of high-energy diffusive motions in the relaxation mechanism at high temperature.\(^3\)
Figure 22 2-D MAS exchange spectra for K$_2$Si$_4$O$_9$ at 555 °C. Mixing time: (a) 0.5 s; (b) 4.0 s. [Reproduced with permission from Stebbins et al.]

$^{11}$B NMR, along with $^{29}$Si and $^{27}$Al NMR, has been used to monitor structural changes in borate, borosilicate and boroaluminosilicate liquids. High-resolution experiments using 3QMAS spectroscopy have recently been carried out. This technique allowed BO$_3$ ring sites to be distinguished from nonring sites in a fast-cooled (Na$_2$O)$_0$·4SiO$_2$·0.95H$_2$O glass sample.

Most NMR studies of melts concern oxides, but some nonoxide glasses have also been analyzed. $^{31}$P and $^{75}$Se NMR have been used to measure multiple site exchange in glass-forming melts of phosphorus and selenium.

Table 12 provides a summary of the recent literature on oxide melts and high-temperature glasses.

3.1.10 Hydrated Minerals and Glasses

In this section, the application of $^1$H and $^2$H NMR spectroscopy to the analysis of glasses and minerals is considered. The NMR characterization of water and other fluids trapped in porous materials is a significant area of application which is not covered here. Imaging is considered separately in section 3.3. This section covers NMR analysis of water and hydroxy groups in hydrated minerals and glasses from a structural point of view, as summarized in Table 13.

$^1$H wideline NMR spectra of hydrous silicates can show Pake patterns typical of immobilized protons. Mobile water and the Si--OH protons with which it is in fast exchange show narrow, motionally averaged line shapes. Superposition of both types of line shape is common in heterogeneous materials. Static $^1$H line shape studies have proved useful in determining the orientation of water in hydrated layers in sheet silicates and to investigate mobility of water in hydrated silicates more generally.

In $^1$H MAS spectra, spinning speeds high enough to remove the homonuclear dipole–dipole couplings would need to be of the order of 30–40 kHz. MAS spectra at lower spinning speeds therefore contain a series of spinning sidebands. They nevertheless have sufficient resolution to distinguish water and silanol OH groups in hydrated silicates. The $^1$H MAS spectrum of a hyalite mineral consisted of three partly overlapping signals at 7.1, 5.6 and 3.9 ppm, which were assigned to isolated water molecules, water clusters and two types of silanol groups. Multiple pulse techniques such as CRAMPS enable sidebands to be suppressed and provide higher resolution, but in amorphous glasses, chemical shift dispersion may still make it difficult to resolve different OH species. 2-D CRAMPS MAS correlation spectroscopy enables the individual MAS spectra of the OH sites to be separated, permitting analysis of the spinning sideband patterns. Figure 23(a) and (b) shows MAS slices from a CRAMPS MAS correlation spectrum of an Na$_2$O·4SiO$_2$·0.7H$_2$O glass, showing the separated spectra for H$_2$O at 4.0 ppm and OH at 14.0 ppm.

$^1$H relaxation measurements ($T_1$ and $T_2$) are used to investigate water mobility in hydrated glasses, minerals and gels. In heterogeneous systems, where water in different phases is not in fast exchange, multiple relaxation times can be resolved. This has been used to good effect in studies of the curing of cement, where relaxation times were used to distinguish three separate phases.

$^2$H has spin $I = 1$ and has a much lower gyromagnetic ratio than $^1$H. Its spectra and relaxation properties are therefore dominated by quadrupolar rather than dipole–dipole interactions. $^2$H NMR of isotope-enriched samples therefore finds some useful applications in investigating hydration sites in glasses and minerals. $^3$H static NMR line shapes give typical powder patterns for immobilized molecules and partially averaged quadrupolar splittings in the presence of molecular motion. D$_2$O in clay minerals shows residual quadrupolar splittings of between 100 Hz and 12 kHz depending on the water content.$^{121}$ $^2$H relaxation is dominated by quadrupolar interactions and relaxation studies provide a useful probe of water mobility in deuterated materials.$^{121, 122}$

3.2 Nuclear Magnetic Resonance Relaxation Applications for Mobile Ions in Glasses

The mobility of nonframework ions in silicates and more generally of both cations and anions in ion-conducting glasses has predominantly been investigated using NMR relaxation measurements. Li$^+$ is the conducting species in a large range of ion-conducting glasses and hence the NMR relaxation properties of its two NMR-active nuclei ($^6$Li and $^7$Li) are extensively used to characterize the structure and dynamics of these materials.

$^7$Li is the more abundant isotope and has spin $I = \frac{3}{2}$. Peak broadening due to quadrupolar interactions and disorder in glasses, along with a narrow chemical shift dispersion, means that structural information is not easy to obtain.$^{(123)}$ On the other hand, $^7$Li relaxation measurements are extremely useful in studying Li$^+$ dynamics. $^7$Li quadrupolar interactions and chemical shift anisotropy are both relatively small in solids, so that relaxation is dominated by homonuclear dipole–dipole interactions. Coupling to paramagnetic centers is important in naturally occurring minerals.$^{(70)}$ $^6$Li and $^7$Li have complementary NMR properties so that a combination of $^6$Li chemical shift and $^7$Li relaxation measurements can provide a more detailed insight into structure and dynamics in Li$^+$ conducting glasses. Figure 24 shows the resolution of Li coordination sites in the MAS spectrum of $^6$Li-enriched lithium orthosilicate.

$^6$Li 2-D exchange spectroscopy in lithium orthosilicate enabled exchange rates and activation energies for exchange between different Li sites to be determined.$^{(42)}$ Close agreement was found between the activation energy for LiO$_3$ to LiO$_4$ exchange with that for conductivity.

The relaxation behavior of framework nuclei, particularly ³¹P in phosphate glasses, has also been shown to give useful insights into ion conduction mechanisms. Spin–lattice relaxation of ³¹P in the rotating frame (T₁r) proved the most suitable method of investigating the effect of Li⁺ dynamics on the glassy framework in LiPO₃. Since rotating frame relaxation is sensitive to motions in the kilohertz range, this enabled a full temperature dependence study of the relaxation to be carried out, whilst maintaining the temperature below Tg. The derived activation energy was in good agreement with that obtained for lithium ion diffusion from conductivity measurements.

Mixed-alkali glasses show a nonlinear dependence of thermal and electrical conductivity properties on cation composition. Cation mobility is also reduced compared with single-ion glasses. Numerous NMR studies have sought to understand the origins of these effects in terms of cation site distributions or the presence of distinct cation environments. It has proved difficult to directly observe distinct sites in NMR spectra of these mixed-alkali systems due to poor chemical shift resolution in 1-D spectra of ions such as ⁷Li⁺ and ²³Na⁺. Recently, a detailed comparison was made between the speciation information obtained from 1-D ²³Na and ³¹P MAS spectra. Inclusion of DAS enhanced the spectral resolution but not sufficiently to allow the detection of inequivalent Na sites. However, the 2-D technique of ²³Na–³¹P DAS/CPMAS HETCOR enabled ²³Na nuclei associated with Q₁ and Q₂ phosphate sites to be separated and the spectra of these fractions showed splittings attributed to distinct Na environments.

The question of cation clustering in mixed alkali metal silicate and chalcogenide glasses has been addressed by ²³Na⁶Li and ²³Na⁷Li SEDOR spectroscopy. Generally, there is no evidence for cation clustering in these systems, although if clustering occurs, the NMR experiments are consistent with preferential interactions of like cations.

Lithium-doped chalcogenide glasses are generally more conducting than their oxide counterparts and there is a considerable literature on lithium ion mobility in thioborates, thigermanates and thiosilicates, as well as oxides and silicates, as summarized in Table 14. Other important nuclei for investigation of cation-conducting glasses are ²³Na and ¹⁰⁹Ag, and ⁸²Rb, ¹³³Cs and ²⁰⁵Tl have also found a few applications.

Some ¹⁰⁹Ag NMR studies have been carried out on silver borate, phosphate and thigermanate glasses. Ag has a low gyromagnetic ratio and slow relaxation times but motional line narrowing in Ag⁺ conducting materials...
3.3 Nuclear Magnetic Resonance Imaging

NMR imaging (NMRI or MRI) is becoming an increasingly important approach to the analysis of heterogeneous inorganic materials. Key reviews are listed in Table 1 and applications from the recent literature of relevance to inorganic oxides and minerals are summarized here (Table 15). Imaging of liquids in porous materials is an important area which is covered in more detail elsewhere.

Applications concerning the hydration and dehydration of oxide materials are well represented by studies on cement and concrete. Figure 26 shows 1-D STRAFI $^1$H images of the penetration of water into two cylinders of Portland cement previously hydrated with $D_2O$. $^1$H relaxation time mapping using single-point imaging (SPI) techniques have also been applied to imaging of protons in concrete, enabling nuclei with fast relaxation times to be imaged (Table 15). Imaging of protons in hydrous minerals has been demonstrated for the first time, in samples of stilbite, agate and enhydros from geothermal fields. Again this required techniques for
imaging nuclei with short $T_2$ values; a spatial resolution of 0.31 mm was reported.\footnote{132} Drying of sodium silicate films was monitored using STRAFI. Spatially resolved $T_2$ images allowed the drying of the films to be investigated as a function of temperature.\footnote{133}

Solid-state imaging has not yet found widespread applications but, as mentioned in section 2.13, the range of nuclei which can potentially be detected include several of importance in inorganic oxides and minerals. $^{11}$B imaging of solids such as borax having boron at sites of low symmetry has been demonstrated using STRAFI.\footnote{134} It is also clear that techniques already developed for imaging of bone minerals, for example, should be directly applicable to a much wider range of minerals and glasses. The difference in the $^1$H--$^{31}$P CP efficiency in protonated compared with unprotonated phosphate ions was used to selectively image brushite and hydroxyapatite minerals.\footnote{135} Continuing developments in this field demonstrate the value of this approach in phosphate imaging,\footnote{136} although extension to a wider range of materials has not yet occurred.
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

4 FUTURE TRENDS

NMR spectroscopy, after 55 years of development, is now a mature technique which is routinely providing a great deal of structural, dynamic and quantitative information about glasses and geological materials. Commercial instrumentation is widely available, and the MAS experiment with a wide range of spin = ½ nuclei is easily implemented by the nonspecialist. MAS probes are available with large volumes for high sensitivity, or with high speeds for high resolution, and the ever increasing magnetic field strengths available in superconducting magnets enhance both sensitivity and resolution.

In terms of spectroscopy, further advances in probe design for high-temperature in situ measurements will encourage wider use of NMR to study phase transitions, melts and high-temperature cation mobilities. The most striking advances in the past 5 years have come, however, in the observation of quadrupolar nuclei. The ability to extract not only chemical shift information but also quadrupole parameters makes such nuclei particularly powerful probes of local structure in solids. The techniques of DOR, DAS and MQMAS are all at a relatively early stage in their development, and many further developments in the design of both hardware and pulse sequences can be anticipated. The routine availability of these techniques to materials scientists will stimulate progress also in the theoretical understanding of structure and dynamics in noncrystalline materials.

One area of application which seems likely to make a large future impact is that of NMR imaging. It is clear from the recent literature that solid-state imaging techniques developed for bone minerals, for example, should also

The fundamental parameters that reproduce a nuclear magnetic resonance (NMR) spectrum in gases, liquids, and solids are the four tensor quantities: the NMR chemical shift of the nucleus, the indirect nuclear spin–spin coupling, the nuclear electric quadrupole coupling, and the direct dipolar coupling tensors. The first three are intimately related to the local electronic structure at the nucleus and the chemical bonds connecting the nuclei. On the other hand, the direct nuclear spin dipole–dipole interaction depends directly and entirely on the third power of the inverse of the direct through-space distance between two nuclei, whether bonded or otherwise. In gases and in liquids where free tumbling of the molecules bearing the nuclear spins leads to isotropic averaging of these quantities, only the isotropic average values, the average of three components along the principal axes of the chemical shift and the indirect spin–spin coupling tensors determine the observed frequencies in the NMR spectrum. In the solid state, restricted motion permits the tensors to manifest all the components, whether the sample is a polycrystalline powder, an amorphous solid, or a single crystal. Theoretical calculations of the NMR chemical shift, indirect spin–spin coupling, and nuclear quadrupole coupling parameters, using quantum mechanical methods, permit the prediction of NMR spectra and provide the physical basis for the relationship between the parameters and molecular electronic structure, which may include local electronic structure (electronic distribution in the immediate vicinity of the nucleus and neighboring bonds), local molecular geometry, bond connectivities, stereochemical structure, as well as subtle...
effects of the chemical environment, such as contributions from remote parts of the molecule, tertiary and secondary structure, crystal packing, solvent effects, and isotopic substitution.

1 INTRODUCTION

The fundamental parameters that reproduce a NMR spectrum in gases, liquids, and solids are: the NMR chemical shift of the nucleus, the indirect nuclear spin–spin coupling, and the nuclear quadrupole coupling. All these quantities are tensors whose directional properties are intimately related to the local electronic structure at the nucleus. In gases and in liquids where free tumbling of the molecules bearing the nuclear spin leads to isotropic averaging of these quantities, only a single number determines the frequencies in the NMR spectrum. The isotropic shift is usually expressed in ppm, to a chosen reference substance in a chosen medium. The chemical shift of the nucleus, the indirect nuclear spin–spin coupling, and the nuclear quadrupole coupling. All these quantities are tensors whose directional properties are intimately related to the local electronic structure at the nucleus. In gases and in liquids where free tumbling of the molecules bearing the nuclear spin leads to isotropic averaging of these quantities, only a single number determines the frequencies in the NMR spectrum.

1.1 Absolute Shielding Tensor and Nuclear Magnetic Resonance Chemical Shift

The NMR spectrum provides the chemical shift δ relative to a chosen reference substance in a chosen medium. The definition of the chemical shift, usually expressed in ppm, is given in Equation (1)

\[ \delta \equiv \frac{\nu - \nu_{\text{ref}}}{\nu_{\text{ref}}} \]  

where \( \nu \) is the resonance frequency for the nucleus of interest in the sample and \( \nu_{\text{ref}} \) is the resonance frequency for the reference. The resonance frequency is determined by a fundamental molecular electronic property called the nuclear magnetic shielding, \( \sigma \), which is defined by the Hamiltonian for the energy of a single nucleus \( N \) possessing a nuclear magnetic moment \( \mu_N \), in an external magnetic field \( B \), Equation (2) (where \( Z \) stands for Zeeman and CS stands for Chemical Shift)

\[ Z_{\text{CS}} = -\mu_N(1 - \sigma)B \]  

The magnetic field experienced by the nucleus at its site is different from the applied magnetic field \( B \) because of the small field \( B_{\text{local}} \) arising from the circulations of the electrons induced by the external magnetic field, Equation (3)

\[ (B_{\text{local}})_\alpha = (1 - \sigma)_{ab}B_\beta, \quad \alpha, \beta = x, y, z \]  

Thus, Equation (4)

\[ CS = +\mu_\sigma \sigma B \]  

The term “magnetic shielding” implies that the magnetic dipole of a nucleus at that site would be shielded from the full effect of the external field by the influence of the induced electronic motions. For free atoms \( \sigma \) is always positive because this circulation generates a shielding field which opposes the applied field. In a molecule the presence of other nuclei hinders this circulation to an extent that depends on the electronic distribution and may even lead to a negative \( \sigma \). Depending on the symmetry of the electronic distribution at the nuclear site, some of the components \( \sigma_{\text{ref}} \) may be zero or identical. For example, for a linear molecule there are only two unique components, \( \sigma_{xx} \) and \( \sigma_{zz} \), where \( z \) is along the molecular axis; these components are designated as \( \sigma_0 \) and \( \sigma_z \), respectively.

Theoretical calculations of the nuclear magnetic shielding provide the entire shielding tensor \( \sigma \) on an absolute basis, i.e. with respect to a bare nucleus. The chemical shift \( \delta \) expresses a difference in nuclear magnetic shielding, Equation (5)

\[ \delta \equiv \frac{\nu - \nu_{\text{ref}}}{\nu_{\text{ref}}} = \frac{\sigma_{\text{ref}} - \sigma}{1 - \sigma_{\text{ref}}} \]  

Usually, though not always, \( \sigma_{\text{ref}} \) can be neglected relative to 1.0, so sometimes it is sufficient to use Equation (6),

\[ \delta \approx (\sigma_{\text{ref}} - \sigma) \]  

A negative chemical shift means that the nucleus located at site A sees a more shielded (smaller) magnetic field than does the nucleus in the reference substance, so that the applied field has to be made higher in order to achieve resonance with the nuclear spin energy separation at site A.

We see from Equation (2) that the mathematical terms in the total energy of a molecule that are bilinear in the external homogeneous magnetic field \( B \) and the nuclear magnetic moment \( \mu \) determine the nuclear magnetic
shielding $\sigma$ for a nucleus in a molecule. The theoretical calculation of NMR chemical shifts from first principles therefore consists of collecting all such bilinear terms in the energy of a molecule in the presence of both an external magnetic field and a nuclear magnetic moment located at the observed site to obtain the absolute shielding tensor quantities $\sigma$. A separate calculation is required for the reference molecule. The NMR chemical shift tensor can then be calculated from differences between $\sigma$ and $\sigma_{\text{ref}}$.

1.2 Indirect Spin–Spin Coupling Tensor

Usually, more than one nuclear spin is present in the observed molecule. The interaction of nuclear spins $N$ and $N'$ is composed of a direct through-space dipolar coupling (coupling of the bare nuclear magnetic dipole moments) and an indirect interaction by way of the electrons. The Hamiltonian for this interaction energy is, Equation (7)

$$D_{IJ} = \mu_N (D + J) \mu_{N'}$$  \hspace{1cm} (7)

The direct dipolar coupling tensor $D$ is symmetric with the principal components summing to zero (a traceless tensor), and depends entirely on the distance vector between $N$ and $N'$. In an oriented system both $D$ and $J$ (the spin–spin coupling) contribute to the observed spectrum. In a rapidly tumbling molecule in solution, only the isotropic average of $J$ survives ($J_{\text{iso}} = (1/3)[J_{xx} + J_{yy} + J_{zz}]$); the anisotropic part averages to zero. A positive $J$ results from an interaction which minimizes the energy when the two nuclear spins are antiparallel. Theoretical calculations of the $J$ tensor from first principles consists of collecting all such bilinear terms in the energy of a molecule, as shown in Equation (7).

1.3 Electric Field Gradient Tensor and Nuclear Quadrupole Coupling Constant

All nuclei with spin $I > 1/2$ have an ellipsoidal distribution of charge and an electric quadrupole moment $eQ$, where $e$ is the magnitude of the charge of an electron. $Q$ is positive if the nucleus is prolate (cigar-like), negative if oblate (pancake-like). $Q$ is an intrinsic property of the nucleus. Energy is minimized by appropriate alignment of an electric quadrupole in an electric field gradient. At a nuclear site in a molecule, there is an electric field gradient when there is an asymmetry in the charge distribution due to the electrons and other nuclei. This electric field gradient is represented by $eq$. The energy of a nuclear quadrupole is quantized according to its orientation in the electric field gradient, even in the absence of an external magnetic field. The electrostatic energy of interaction between the electric quadrupole moment and the electric field gradient is expressed in terms of the nuclear quadrupole coupling constant $(e^2Qq_{zz}/\hbar)$.

The magnetic dipole moment of a quadrupolar nucleus is along the axis of symmetry of the nuclear charge distribution. Thus, when a quadrupolar nucleus is placed in a magnetic field so that the nuclear magnetic dipole tends to align with the external magnetic field, the interaction of the electric quadrupole with the internal electric field gradient at the nuclear site in the molecule affects the nuclear magnetic energy levels. The tensor coupling between the nuclear spin and the electric field gradient $eq$ at the nucleus is described by the Hamiltonian, Equation (8)

$$q = I_N \frac{eQ}{2I(2I-1)} eq_{1N}$$  \hspace{1cm} (8)

Like $D$, the electric field gradient tensor is traceless: the isotropic average of energy terms involving $q$ is zero. Thus, in liquids or gases the positions of the lines in the NMR spectrum are not affected by the nuclear quadrupole coupling. In solids the nuclear quadrupole coupling can dominate the NMR spectrum and measurements of the nuclear quadrupole coupling tensor in single crystals or powders provide the electric field gradient tensors.

1.4 Nuclear Magnetic Resonance Parameters in Gases, Liquids, and Solids

In gases and liquids, isotropic averaging caused by the rapid tumbling of molecules leads to observations of only the isotropic part of $\sigma$ and $J$, which are given by one third the sum of the principal components of these tensors. At the same time, $D$ and $q$ being traceless means that this sum is zero. Thus, in liquids or gases the positions of the lines in the NMR spectrum are not affected by either the direct dipolar coupling or the nuclear quadrupole coupling. To a good approximation, neither the chemical shift nor the spin–spin coupling $J$ is dependent on the strength of the magnetic field. Actually, one has to be quite specific in defining the environment of the nucleus in both sample and reference because the NMR chemical shift is very sensitive to these. For example, the chemical shift of a $^{13}$C nucleus in molecule $A$ relative to the usual reference, tetramethylsilane (TMS) is $\delta_A = \sigma(^{13}C, \text{in TMS, in CDCl}_3, 300 \text{K}) - \sigma(^{13}C, \text{in } A, \text{in CDCl}_3, 300 \text{K})$.

It is important to specify completely all the variables (e.g. mole fractions $x_A$, etc.) that determine the observed chemical shift because the nuclear magnetic shielding is so sensitive to factors of molecular structure and environment. There is an intrinsic mass and temperature dependence of the chemical shift, the spin–spin coupling, and the nuclear quadrupole coupling because all three are functions of the electron distribution, which in
turn is a function of the nuclear positions. As the internuclear separations are weighted according to the vibrational functions, the thermal average values of these NMR parameters are dependent on the vibrational and rotational state populations. Furthermore, all three NMR parameters are dependent on the medium since each one is affected by the electronic environment, and the electron distribution is affected by intermolecular interactions and external electric fields. For protons the medium effects are generally small, whereas they can be quite large for other nuclei.

In oriented molecules, such as in liquid crystal solutions, polycrystalline powders, single crystals, or amorphous powders, the tensor nature of the three NMR parameters manifest themselves in the spectrum. In principle, one can measure both the anisotropy and asymmetry of the J tensor in rigid solids. However, the anisotropy of J transforms similarly to the direct dipolar coupling, thus the two interactions cannot be easily separated via experiment. The anisotropy in J is predicted to become more important for coupling constants involving heavier nuclei, whereas D depends only on the internuclear distance. Rapid magic-angle spinning (MAS) can be used to obtain high-resolution spectra of solids by removing the effects of the anisotropic terms, which in general have a \( P_2(\cos \theta) \) dependence. The angle for which \( (3 \cos^2 \theta - 1) \) equals zero is the magic-angle 54.74°. The terms that give rise to the NMR spectrum of quadrupolar nuclei include in addition, a \( P_4(\cos \theta) \) dependence. Various techniques have been used to determine these three NMR tensors individually by experiment, including the orientations of their principal axis systems. In solids, the spinning sidebands observed in slow MAS NMR spectra arising from tightly J-coupled spin pairs contain valuable information about NMR parameters such as the orientation of chemical shift tensors and the sign of J. Multidimensional NMR spectra in solids permit the separate determination of the isotropic chemical shifts and the anisotropic line shapes that contain chemical shift tensor and quadrupole coupling information for each site.

Thus, we have seen that the parameters of an NMR spectrum are related to fundamental molecular electronic properties: the chemical shift is related to nuclear magnetic shielding \( \sigma \) and the nuclear quadrupole coupling is related to the electric field gradient tensor \( eq \). The indirect spin–spin coupling J is itself a molecular electronic property. Therefore, the general approach to the theoretical calculations of these NMR parameters is through a quantum mechanical calculation of molecular electronic properties in the isolated molecule. Any medium effects that have to be included, when they are large enough, require, in addition, ensemble averages for a gas, liquid, or solution. The calculation of the electric field gradient is simplest, since this is a property of the unperturbed electronic state of the molecule. Since \( \sigma \) and J are electronic properties associated with the presence of magnetic fields and fields generated by nuclear magnetic moments, their calculation requires the general approaches that apply to multiple perturbations. Furthermore, since the probe nucleus senses electronic environments in the immediate vicinity of the nucleus, high-level calculations that take into account electron correlation have to be used for all three parameters to achieve accuracy, and relativistic corrections are sometimes necessary. Density functional methods have been very successful and can compete favorably with ab initio calculations.

### 2 GENERAL THEORETICAL METHODS

The mechanisms by which a nuclear magnetic moment interacts with the molecular field and with external magnetic or electric fields in the ground vibronic state were originally articulated in fundamental work by Ramsey.\(^1\–3\) For a unified approach to molecular electronic properties which explicitly shows where the contributing terms arise and thereby also permits the relationships between electronic properties to be perceived, consult the articles by Michelot.\(^4\,5\) The complete molecular Hamiltonian in the presence of external magnetic and electric fields, including all relevant interaction terms involving nuclear magnetic moments (such as interaction between the nuclear magnetic moment and the field induced at the nucleus by the molecular motion, as well as those related to the interaction of the magnetic moment induced by this molecular motion with an external magnetic field), treats electrons and nuclei as Dirac particles. Relativistic effects are included from the beginning and effects due to the finite dimensions of nuclei are also taken into account, so that the nuclear quadrupole coupling is a natural outcome.\(^4\) Using this Hamiltonian with relativistic corrections for a free molecule in a nondegenerate electronic state, a second-order calculation in degenerate perturbation theory leads to the explicit expressions for the contributing terms to nuclear magnetic shielding \( \sigma \), indirect spin–spin coupling J, nuclear electric quadrupole coupling, and all other molecular electronic properties.\(^5\)

#### 2.1 Multiple Perturbation Theory

All the terms in the molecular Hamiltonian given by Michelot\(^4\) may be treated as perturbations added to a zeroth-order part (the kinetic energy of the electrons together with the total coulomb potential energy of all the electrons and nuclei, assumed to have already been solved). These include terms bilinear in \( \mu_B \) and B. In first order, these will lead to energy terms that are of the form...
given by Equation (4), providing the formal expression for the so-called diamagnetic part of the nuclear magnetic shielding \( \sigma \). In second order, the terms in the molecular Hamiltonian that are linear in \( \mu_0 \) together with those linear in \( \mathbf{B} \) will lead to energy terms that are also of the form given by Equation (4), providing the formal expression for the so-called paramagnetic part of the nuclear magnetic shielding \( \sigma \). Michelot's expression derived for nuclear magnetic shielding \( \sigma \) reduces to that given by Ramsey\(^{(1,2)} \) if the origin of the molecular frame is placed at the center of the nucleus of interest, the orientation being that of the Eckart frame. Formally, the shielding term for nucleus \( N \) is given by Equation (9):

\[
\sigma_{ab}(N) = \frac{\mu_0 e^2}{8\pi m} \sum_k \{ (r_{kN} \cdot \mathbf{r}_0) r_{kN}^{-3} \delta_{ab} - (\mathbf{r}_{kN} \cdot \mathbf{r}_0) r_{kN}^{-3} \} - \frac{\mu_0 e^2}{8\pi m} \sum_{n \neq 0} (\mathbf{E}_n - \mathbf{E}_0)^{-1} \\
\times \{ 0 \} \sum_k r_{kN}^{-3} L_{kN}^a |n\rangle \langle n| \sum_j L_{j0}^a |0\rangle \\
+ \{ 0 \} \sum_j L_{j0}^a |n\rangle \langle n| \sum_k r_{kN}^{-3} L_{kN}^a |0\rangle.
\]

(9)

The first index \( a \) (\( x, y, z \)) is associated with the nuclear magnetic moment and the second index \( b \) (\( x, y, z \)) is associated with the external magnetic field. \( L_{j0}^a \) is the \( a \) component of the orbital angular momentum operator for the \( j \)th electron with respect to the chosen origin (so-called gauge origin) and \( r_{0N} \) is the distance vector between the \( k \)th electron and the origin. \( L_{kN}^a \) is the \( a \) component of the orbital angular momentum operator for the \( k \)th electron with respect to the nucleus \( N \) as origin. \( r_{kN} \) is the distance vector between the \( k \)th electron and the nucleus \( N \). \( m \) and \( e \) are the mass and charge of the electron, \( \mu_0 \) is the magnetic permeability of a vacuum. \( E \) stands for the energy at states 0 and \( n \) (0 is the lowest state and \( n \) is an index that runs through all the states of the molecule). In Equation (9) the second term in the sum over states (SOS) form, that is, in terms of the symbol \( |n\rangle \) over all excited states designated by the symbol \( |n\rangle \). In the symbol \( |0\rangle \) the operators for the angular momentum and the distance vector for the electrons are integrated over the ground state \( |0\rangle \) and the excited state \( |n\rangle \).

In the same way, the terms in the molecular Hamiltonian that are bilinear in \( \mu_\mathbf{N} \) and \( \mu_\mathbf{N} \) lead to the energy terms that are already of the form given by Equation (7) give rise to the first order part of the indirect spin–spin coupling \( \mathbf{J} \), usually denoted by \( \mathbf{J}^{(1)} \). The terms linear in \( \mu_\mathbf{N} \) in the molecular Hamiltonian in the nonrelativistic limit are three, labeled orbital, spin dipolar (SD), and Fermi contact (FC). In second order, products of these lead to various contributions to the spin–spin coupling \( \mathbf{J} \). The product of orbital terms leads to \( \mathbf{J}^{(1b)} \); \( \mathbf{J}^{(1a)} \) is sometimes called the diamagnetic orbital (OD) contribution or \( \mathbf{J}^{(OD)} \), and \( \mathbf{J}^{(1b)} \) the paramagnetic orbital (OP) contribution or \( \mathbf{J}^{(OP)} \) because of the analogy with the diamagnetic and paramagnetic parts of the shielding tensor. The product of SD terms leads to \( \mathbf{J}^{(2)} \) or \( \mathbf{J}^{(SD)} \), and the product of FC terms leads to \( \mathbf{J}^{(3)} \) or \( \mathbf{J}^{(FC)} \). By symmetry, there is only one nonvanishing cross-term, resulting from the product of the SD and the contact terms, referred to as \( \mathbf{J}^{(4)} \). \( \mathbf{J}^{(FC)} \) is purely scalar (isotropic), whereas the others are anisotropic. The motional average of \( \mathbf{J}^{(4)} \) is zero, thus, all but \( \mathbf{J}^{(4)} \) contribute to the observed isotropic average spin–spin coupling for a rapidly tumbling molecule in solution. All terms contribute to the observed NMR spectrum in solids. The formal expressions for spin–spin coupling in the nonrelativistic limit are shown below in terms of the spin \( \mathbf{S}_k \) and orbital \( (L_{kN}^a) \) angular momentum of the \( (k) \)th electron, Equations (10) to (14):

\[
\mathbf{J}^{(1a)}_{ab} = \frac{2m}{h} \frac{\mu_0^2}{4\pi} \frac{\mathbf{P}_\mathbf{N}}{2} \mathbf{Y}_\mathbf{NN} \{ 0 \} \sum_k r_{kN}^{-3} r_{kN}^{-3} \\
\times \left[ (r_{kN} r_{kN}^\perp) \delta_{ab} - r_{kN}^\perp r_{kN}^\perp \right] |0\rangle
\]

(10)

\[
\mathbf{J}^{(1b)}_{ab} = \frac{(2\mu_0 h)^2}{h} \frac{\mathbf{P}_\mathbf{N}}{4\pi} \mathbf{Y}_\mathbf{NN} \sum_n (\mathbf{E}_n - \mathbf{E}_0)^{-1} \\
\times \{ 0 \} \sum_k r_{kN}^{-3} L_{kN}^a |n\rangle \langle n| \sum_j L_{j0}^a |0\rangle + cc
\]

(11)

\[
\mathbf{J}^{(2)}_{ab} = -\frac{1}{h} (2\mu_0 h)^2 \frac{\mathbf{P}_\mathbf{N}}{4\pi} \mathbf{Y}_\mathbf{NN} \sum_n (\mathbf{E}_n - \mathbf{E}_0)^{-1} \\
\times \{ 0 \} \sum_k 3r_{kN}^{-5} (\mathbf{S}_k r_{kN}) r_{kN}^a r_{kN}^a - r_{kN}^{-3} \mathbf{S}_k^a |n\rangle \langle n|
\]

(12)

\[
\mathbf{J}^{(3)}_{ab} = -\frac{1}{h} \frac{16\pi \mu_0 h}{3} \frac{\mathbf{P}_\mathbf{N}}{4\pi} \mathbf{Y}_\mathbf{NN} \\
\times \sum_n (\mathbf{E}_n - \mathbf{E}_0)^{-1} \{ 0 \} \sum_k \delta(r_{kN}) \mathbf{S}_k^a |n\rangle \langle n|
\]

(13)
where \( \text{cc} \) indicates the conjugate term in which the two operators are switched. \( \mu_B \) is the Bohr magneton, \( \gamma_N \) is the magnetogyracic ratio for the nucleus \( N \), \( \delta(r_{\text{NN}}) \) is the Dirac delta function which picks out the value at \( r_{\text{NN}} = 0 \) in any integration over the coordinates of the \( k \)th electron.

The coupling contributions \( J^{(1a)} \) or \( J^{(OD)} \) and \( J^{(1b)} \) or \( J^{(SD)} \) can be thought of as arising through paramagnetic and diamagnetic currents induced in the molecular electronic distribution by the nuclear magnetic moment of one of the nuclei, coupling to the magnetic moment of the other nucleus. The coupling contribution \( J^{(3)} \) or \( J^{(FC)} \) can be considered as arising from the transmission of spin information from nuclear spin to electron spin. Owing to the finite density of the electron at the nucleus, this information is passed on through the spin interaction between electrons in the molecule and transmitted at the other end via electron spin density at the other nucleus. The dipole–dipole interaction between the nuclear and electronic distribution by the nuclear magnetic moment are then evaluated, using those electronic properties that can be calculated as an average over the electronic ground-state wavefunction.

The calculation of the electric field gradient tensor does not require a perturbation treatment since this is one of those electronic properties that can be calculated as an average over the electronic ground-state wavefunction. The \( \varepsilon_{z z} \) component of the electric field gradient tensor is given by Equation (15)

\[
q_{zz} = \sum_j e_j (3z_j^2 - r_j^2)r_j^{-5}
\]

where \( e_j \) is the charge of the \( j \)th particle (the electrons, other nuclei, external charges) in the system and the \( z \) axis is in the nuclear-fixed coordinate system, that is along the nuclear axis of spin. The spin axis of the nucleus is allowed to rotate with respect to the laboratory frame of reference and the nuclear wavefunction will be a product of the intrinsic \( \Psi_{\text{intrinsic}} \) and orientation \( \Psi_{l,M} \) functions for spin angular momentum described by quantum numbers \( l \) and \( M \), Equation (16)

\[
\Psi_{\text{total}} = \Psi_{l,M}\Psi_{\text{intrinsic}}\Phi(\text{electrons, other nuclei, external charges})
\]

For a nucleus in a molecule oriented in the laboratory framework, the components of the field gradient tensor are \( q_{xx}, q_{yy}, q_{zz} \). The principal field gradient tensor component \( q_{zz} \) is related to the laboratory values through the direction cosines between the axes, as follows, Equation (17):

\[
q_{zz} = (C_{XX})^2 q_{xx} + (C_{YY})^2 q_{yy} + (C_{ZZ})^2 q_{zz}
\]

In the absence of a magnetic field, the energy of a quadrupolar nucleus in the electric field gradient will be obtained by averaging the electric quadrupole charge over the wavefunction \( \Psi_{\text{intrinsic}} \), averaging the squares of the direction cosines over \( \Psi_{l,M} \), and averaging \( q_{zz} = e_j (3z_j^2 - r_j^2)r_j^{-5} \) over the wavefunction \( \Phi \) (electrons, other nuclei, external charges) expressed in the laboratory frame. The average of the direction cosines over \( \Psi_{l,M} \)
leads to an energy expression that is proportional to \([3M^2 - I(I + 1)]\) in the absence of a magnetic field.

In the presence of a magnetic field, the magnetic dipole moment of a quadrupolar nucleus, which lies along the axis of symmetry of the cigar-like or pancake-like nuclear charge distribution, interacts with the magnetic field. Thus, when a single quadrupolar nucleus in a molecule is placed in a magnetic field, the interaction of the electric quadrupole with the internal electric field gradient at the nuclear site in the molecule leads to a series of 2I resonance lines. Thus, a spin \(I = 1\) nucleus in an axially symmetric electric field gradient gives a pair of lines separated by \([e^2 q_{zz} Q]/3(2)\) or more explicitly, by \([e^2 q_{zz} Q](3/2)(3 \cos^2 \theta - 1)/2\), where \(\theta\) is the angle that the principal symmetry axis of the electric field gradient makes with the external magnetic field. The pair of lines is centered at a frequency that provides the shielding tensor. Both the shielding tensor and the electric field gradient tensor in the XYZ (i.e. the laboratory-fixed) coordinate system can be obtained from an oriented molecule in the solid state. Equation (17) permits the determination of the tensor in the xyz (i.e. the molecule-fixed) coordinate frame system. Since the electric field gradient is a traceless tensor, the isotropic average is zero. Thus, in the liquid phase the positions of the lines in the NMR spectrum are not affected by the nuclear electric field gradient.

Theoretical calculations of the electric field gradient tensor in the molecular frame of an isolated molecule involves evaluating the quantum mechanical average of the operator \(q_{zz} = q_{ij}(3z^2_i - r_i^2) r_j^{-5}\) over the ground state electronic wavefunction for the molecule, where \(j\) runs over all electrons and the origin is set at the nucleus in question. To this electronic contribution must be added the nuclear contribution, by evaluating a similar algebraic expression in which \(e_i\) are the charges of the other nuclei and \(z_i\) and \(r_i\) are their positions in the molecular framework with the origin at the nucleus in question. For molecules in a liquid, electric field gradient contributions from neighbors have to be included, which may require a quantum mechanical average or an approximate sum over fixed partial charges.

2.2 Gauge Origin Problem in Calculations of Chemical Shift

In deriving the expressions shown here, the external magnetic field \(\mathbf{B}\) itself does not appear in the Hamiltonian. What appears instead are the magnetic vector potentials associated with the magnetic fields, Equation (18):

\[
\mathbf{B} = \nabla \mathbf{A} \tag{18}
\]

where \(\nabla\) is the gradient vector. That is, \(B_z = (\partial A_y/\partial x) - (\partial A_x/\partial y)\), for one component. While \(\mathbf{B}\) is determined uniquely if \(\mathbf{A}\) is given, unfortunately there is an ambiguity because there is no unique \(\mathbf{A}\) that produces a given \(\mathbf{B}\). Any transformation that takes a particular \(\mathbf{A}\) into another functional form that also reproduces the same \(\mathbf{B}\) upon applying Equation (18) is called a gauge transformation. A mere translation of the origin of the coordinate system can do this, therefore the set of problems associated with this ambiguity is called the gauge origin problem. Physically, there should be no problem at all, since an arbitrary choice of coordinate system should not affect an observable property. Similarly, theoretically there should be no problem at all; any physical quantities resulting from any calculations involving \(\mathbf{A}\) or \(\mathbf{B}\) or physical quantities related to them must be gauge invariant, provided the calculations are done exactly. In fact, calculations are not usually done exactly when one uses an incomplete set of basis functions in which to do the calculations. It has been shown that if the Hartree–Fock equations are solved exactly (which is only possible in the limit of a complete basis) the total current density is gauge independent, as is the nuclear magnetic shielding \(\sigma\), while the two parts which are usually called the “diamagnetic” and “paramagnetic” contributions in Equation (18) are not individually gauge invariant. In practice, calculations are not carried out in the Hartree–Fock limit so the results of such calculations are not gauge invariant. When a single origin is chosen common to all electrons in the molecule in the definition of \(L_{j 0}\) (and \(r_0\)), the method is the so-called “common origin” coupled Hartree–Fock (CHF) method.

Consider an isolated atom. The external magnetic field induces a current density. The current density vector is orthogonal to the magnetic field vector \(\mathbf{B}\) and to the position vector \(r_j\). For a magnetic field in the \(z\) direction the current density vectors lie in planes parallel to the \(xy\) plane, following the tangents of concentric circles. Here, the natural choice of origin is the position of the nucleus; this leads to a vanishing paramagnetic current density. The current density is entirely the diamagnetic part and corresponds to a local field that opposes the external field \(\mathbf{B}\). Moving the origin off-center to other than the position of the nucleus would make the two parts more difficult to evaluate, but the sum should still be the same as before, so there is no reason to adopt an alternative origin. In molecules, however, there is no choice of origin that will make the paramagnetic part vanish. Changing the location of the origin, in the definition of \(r_0\) and \(L_{j 0}\) in Equation (18) leads to differing amounts of positive and negative terms. The worst choice gives very large not quite canceling terms. Clearly, the inner shell electrons in a molecule behave like they do in the free atom, so that it makes sense to choose the nucleus as the origin when
calculating integrals over orbitals centered on that atom. However, that same origin would be a bad choice for orbitals centered on another atom, whereas choosing the nucleus of that atom as origin would present a favorable atom-like calculation for its own inner electrons. Thus, it becomes clear that in order to avoid calculating large positive and negative terms which imperfectly cancel in a single origin method, some method of using distributed origins would present a practical advantage in computing nuclear magnetic shielding for nuclei in molecules.

The theoretical calculations of nuclear magnetic shielding did not become generally practical even for very small molecules until (1) various ways of using distributed origins were devised, and (2) efficient algorithms for evaluating second-order properties were developed. The various schemes for using distributed origins are known by the acronyms LORG (localized orbital/local origin), IGLO (individual gauge for localized orbitals), GIAOs (gauge including atomic orbitals), and IGAIM (individual gauges for atoms in molecules). The success of distributed origins comes from the avoidance of calculating large imperfectly canceling contributions. In the first two methods, gauge factors are applied to localized molecular orbitals instead of every atomic orbital. The LORG and IGLO methods introduce an approximation in the form of the closure relation and LORG uses commutation rules and identities. Both have been very successful, although there is the problem of lack of uniqueness in the localization method used. The GIAO method uses gauge factors on every atomic orbital. Although this method of distributed origins had been introduced much earlier than all the others, it was not until the efficient implementation by Peter Pulay using the analytic gradients approach that it became widely successful. The convergence of calculated \( \sigma \) values with increasing quality of basis set employed appears to be faster with the GIAO method. GIAOs (sometimes called London orbitals) constitute a physically motivated, compact basis set for magnetic calculations. The field-dependent exponential factor in the London orbital depends on the origin of the coordinate system. A displacement of the origin changes the phase factor of an orbital centered on a nucleus by a factor which is independent of the electronic coordinates. Thus, the calculated properties such as shielding remain unaffected and methods based on the use of such orbitals are gauge invariant. The most important property of the GIAO method is not this formal translational invariance but that the GIAO (the atomic orbital multiplied by the gauge factor) itself represents to first order the eigenfunctions of a one-electron system which has been perturbed by an external magnetic field. GIAOs thus incorporate the bulk of the effect of the magnetic field at the basis function level. The IGAIM approach amounts to constructing the induced current density distribution of a molecule from its constituent atoms, following the highly successful atoms-in-molecules concepts of R.F.W. Bader. It differs from LORG, IGLO, and GIAO in that the gauge origins are determined by properties of the charge density in real space rather than by the behavior exhibited by the basis functions in the Hilbert space of the molecular wavefunction. All these distributed origin methods (GIAO, IGLO, LORG, IGAIM) and any single common origin method should lead to identical results at the Hartree–Fock level in the limit of a complete set of basis functions. The differences lie in the rate of convergence as the number of basis functions are increased. The various distributed-origins methods converge toward the Hartree–Fock limit faster than using a single origin. Common origin calculations require much larger basis sets to provide nearly origin-independent results comparable to the results from distributed-origin methods. An alternative method of doing calculations with a single origin is to cast the diamagnetic term in the same (a SOS) form as the paramagnetic term. This makes the rate of convergence of the calculations of the two parts equally slow and the calculations equally difficult. This (Geertsen’s method) has the virtue of being origin-independent (i.e. gives the same answer for any choice of common origin) at any basis set size.

2.3 Difficulties of Describing Triplet States in Calculations of Spin–Spin Coupling

There are no gauge problems in spin–spin coupling calculations; as seen in Equations (10–14) only operators with their origin at the nucleus \( r_{\text{eq}} \) and \( r_{\text{eq}} L_{\text{eq}} \) appear. The calculations of spin–spin coupling have their own associated difficulties. As can be seen in Equations (10–14), the nature of some of the indirect spin–spin coupling mechanisms requires calculations with uncoupled spin states. Thus, the spin-unrestricted approaches that are normally applied to open shell systems have to be used. When there is a nonsinglet ground state with lower energy than the restricted Hartree–Fock singlet ground state, the calculations of the \( J^{\text{SD}} \) and \( J^{\text{FC}} \) terms require higher order calculations than CHF. Furthermore, the usually (not always) dominant FC contribution in Equation (13) requires that the spin densities are highly accurate at the location of the nucleus, and this is not easily achieved when the basis functions used are the standard gaussian form, having no cusp at the nucleus. Relativistic effects influence spin–spin couplings much earlier (at lower atomic numbers) than other properties, owing to the strong dependence of \( J \) on the electronic structure at the position of the nucleus and its immediate vicinity. In fact, Equations (10–14) are valid only for the point nucleus in the nonrelativistic limit. For heavy nuclei it is necessary
to start out with the relativistic treatment described in section 2.6, since the nonrelativistic theory may lead to unrealistic calculated values.\(^{(11)}\)

### 2.4 Ab initio Methods

In ab initio calculations of NMR parameters there are several things that have to be considered: (1) the level of theory that is used (without, with some, or with substantial electron correlation, with or without relativistic corrections), (2) the number of basis functions, (3) the desired degree of averaging over molecular configurations (with or without rovibrational averaging, with or without medium effects), (4) the availability of tensor data, and (5) the availability of absolute shielding test data in the case of chemical shifts. In the case of spin–spin coupling, there is very limited information beyond that of the isotropic average values obtained in solution. Only in extremely rare cases is there anisotropy information, so that the only viable additional tests are those of isotopic effects on spin–spin coupling. In the case of \(^{13}\)C chemical shifts the amount of detailed tensor information from single crystals and polycrystalline powders is so rich that the level of theory, and size of basis sets needed, and the accuracy of geometrical structure data required to achieve agreement with experiment has been established (by D.M. Grant and associates) for a large variety of carbon site types. The level of theory used in ab initio calculations of NMR parameters had to improve continuously with the challenges posed by attempts to match experimental results for specific small molecules, as we shall see below (section 3.1). Depending on the need for accuracy, depending on the nucleus and the nature of the nuclear site, the appropriate level of calculation can be done. Various levels of theory have been used with various numbers of basis functions. The need to establish good basis functions still hinders accurate calculations for transition metal nuclei. Furthermore, in some cases there is a lack of a good test molecule in the gas phase for which absolute shielding has been established. For the purpose of distinguishing between two structures or even two chemical identities, calculations of \(\sigma\) using uncorrelated wavefunctions constructed with smallish basis sets have sometimes been employed. This is a very dangerous approach, which has been criticized. Ideally, a calculation to estimate the importance of electron correlation to the nuclear shielding should be done. An estimate of the magnitude of the effects of averaging over molecular configurations is needed, in order to determine whether it is sufficient to do a calculation for a single molecule at a fixed geometry in a vacuum. An estimate of the magnitude of relativistic effects on shielding is needed when next neighbors are halogen atoms, or when the nucleus is a heavy nucleus. The involvement of multiple bonds or presence of lone pairs at the nucleus of interest is usually an indication that correlated methods have to be used.

An alternative to the CHF approach is the use of polarization propagator or the equation of motion (EOM) methods. With these latter two methods the level of calculation equivalent to the CHF level is the random phase approximation (RPA). For the same basis set, using the same origin choice, calculations using CHF and RPA should provide the same results. In terms of perturbation theory, the RPA is the consistent first-order approximation to the polarization propagator or the EOM. The CHF, RPA, and the first-order polarization propagator method represent the same approximation for frequency-independent properties such as the NMR properties \(\sigma\) and \(\mathbf{J}\). With respect to the extent of inclusion of electron correlation, CHF and RPA provide the first level of calculations.

In the finite field method, the NMR parameter (for example, \(\mathbf{J}\)) is obtained by differentiating the energy in the presence of the nuclear magnetic moments (or in the presence of the nuclear moment and the external magnetic field for \(\sigma\)) with respect to the nuclear moments (or with respect to the nuclear moment and the external field, for \(\sigma\)). The addition of a finite field to the total energy expression is a simple extension of existing computer codes for electronic structure calculations and is one of the standard methods for calculating higher order molecular electronic properties such as the nonlinear polarizabilities, for example. Thus, the finite field method is easily used, without additional theoretical development, to study the effects of electron correlation on properties. The drawback is that a finite field calculation has to be carried out for each tensor component of the property. Thus, while the purely isotropic FC term of \(\mathbf{J}\) is easily done with finite field methods at various levels such as various many body perturbation theory (\(n\)th order term) (MBPT\((n)\)) and various coupled cluster (CC) methods, the tensor types of mechanisms given in Equations (10) to (12) and (14) require several calculations to yield the various \(xx\), \(xy\), \(xz\), \(yy\), \(zz\), components. Direct methods such as the polarization propagator or EOM method on the other hand, use analytic expressions that provide all components of the tensor with one calculation. In an MBPT\((n)\) calculation, or alternatively the Møller–Plesset \(n\)th order term (MP\(n\)) perturbation series, all energy contributions less than or equal to order \(n\) in perturbation theory are included. CC methods on the other hand, in addition to being consistent to a particular order in perturbation theory include certain classes of energy contributions summed to infinite order. The same kind of infinite summations are also included in polarization propagator methods (RPA, SOPPA, etc.). Thus, SOPPA
shielding in the molecule PH$_3$.

Correlation is important for 31P calculations in molecules rated 13C sites, and even olefinic sites. The major problems be adequately described by a single Slater determinant. of shielding, when the electronic ground state cannot (MCSCF) may sometimes be necessary for calculations where MBPT(2) or MP2 level is no longer adequate. With strong correlation effects, that is for those cases convergence of the perturbation series for those systems. MP4 often alternating in sign. Despite its successes, go up to MP4 level, with the corrections at MP2, MP3, MP2 results is not small, then it may be necessary to take care of the dynamic correlation effects and hence provide MP2 level of wavefunctions. These are supposed to improve results for closed shell systems where CHF already gives good results. When the degree of electron correlation effect is to enhance deshielding, while in the nitro nitrogen the correlation effects are to increase shielding. Thus, in (NO)(NO$_2$) the correlation effects are large and opposite in sign for the two types of N. Correlation contributions to the isotropic 15N shielding range are $-558$ ppm in (NO)$_2$, $+61$ ppm in (NO$_2$)$_2$ and $-63$ and $+116$ ppm in (NO)(NO$_2$).

If different electronic configurations dominate the wavefunction at different geometries, the calculation of the shielding surface also requires a computational method based upon a multiconfiguration wavefunction. The MCSCF approaches are hampered by the same sort of problem because rather large active spaces are needed to obtain satisfactorily converged results. While static correlation effects on shielding arising from near degeneracies are efficiently treated by the MCSCF methods described above, many body perturbation theory (MBPT, also known as Möller–Plesset perturbation theory) has been used to treat dynamical correlation effects.

One of the most successful approaches for the treatment of electron correlation is provided by CC theory. While ultimately based on a single determinant reference function, the exponential parametrization of the wavefunction ensures an efficient treatment of electron correlation. In particular, dynamic correlation effects are accounted for with nearly quantitative accuracy at a fraction of the cost needed to obtain similar precision with MCSCF approaches. Among the various schemes suggested in the literature, the CCSD approximation in which single and double excitations are considered in the cluster operator, has proven specially useful in calculations of other molecular properties. CC approaches can be considered as infinite-order generalizations of the MBPT series. The implementation of GIAOs for the CCSD approach has been carried out by Gauss and Stanton.
and further augmented by a perturbative correction for connected triple excitations coupled cluster singles and doubles with some triple excitations (CCSD(T)). The principal advantage of the GIAO method is the ease with which high-level treatments of electron correlation may be handled by straightforward application of analytic derivative theory.

MCSCF/GIAO calculations for triple-bonded systems, in particular HC=N, HN=C, MeC=N, and MeN=C show that the electron correlation effects are large for the triple-bonded nuclei, especially the component perpendicular to the triple bond axis, and largest for the terminal nucleus. For example, the electron correlation contribution to $\sigma_{13}^1$C shielding is $+47$ to $+54$ ppm in the $-N=13$C nuclear sites, and to $\sigma_{13}$ nitrogen shielding is $+87$ to $+79$ ppm in the $-C=N$ sites. These MCSCF/GIAO results do not compare as well with experiments as do the calculations by Gauss using the CCSD method. The ultimate level of theory would be full configuration interaction (FCI), but this is only possible for very small systems and is rarely used.

The same general methods for multiple perturbations are used for calculating spin–spin couplings, with the difference that there are no gauge origin problems in spin–spin coupling calculations. All but the $J^{(OD)} + J^{(OP)}$ mechanisms mix triplet states with the unperturbed electronic singlet ground state. Thus, the unrestricted Hartree–Fock (UHF) method is sometimes used to generate the unperturbed electronic ground state, even for closed shell molecular systems such as CH$_4$. The extent to which electron correlation needs to be included depends on the system, just as in shielding calculations. The same molecules that are found to be pathological in shielding calculations also pose problems in spin–spin coupling calculations. The uncorrelated finite field SCF calculations, which are the same approximation as CHF and RPA calculations, in most cases give good field SCF calculations, which are the same approximation as spin–spin coupling calculations. The uncorrelated finite field SCF calculations also pose problems in the calculations by Gauss using the CCSD method.

The same molecules that are found to be pathological for closed shell molecular systems such as CH$_4$. Thus, the unrestricted electronic singlet ground state. Thus, the unrestricted Hartree–Fock singlet ground state, and to $\sigma_{13}$ nitrogen shielding is $+87$ to $+79$ ppm in the $-C=N$ sites. These MCSCF/GIAO results do not compare as well with experiments as do the calculations by Gauss using the CCSD method. The ultimate level of theory would be full configuration interaction (FCI), but this is only possible for very small systems and is rarely used.

The method is MCLR (multiconfiguration linear response). MCSCF functions have been used for the hydrides of group IV (C, Si, Ge, Sn). Finite field methods have been used by Bartlett et al. to calculate the FC mechanism of spin–spin coupling using various levels including electron correlation, up to CCSD. MBPT has also been used.

2.5 Density Functional Methods

One method of including electron correlation effects is through density functional theory (DFT). DFT methods have become widely used. DFT methods are based on a theorem which states that for a scalar potential $V(r)$ the ground state $N$-electron density uniquely determines the potential that gives rise to it. The total electronic energy is a unique functional of the density $\rho(r)$.

Although constructing an accurate approximation to the kinetic exchange correlation functional $G[\rho(r)]$ is a formidable task, it need only be done once because the form of $G$ is independent of the form of $V(r)$. Approximations are required because the functional is not known exactly but these approximations are getting better and better. Developments in exchange correlation functionals have made DFT methods viable alternatives to those of conventional quantum mechanical calculations. DFT combines the promise of accurate results (that is, more accurate than Hartree–Fock level quantum calculations) with cheaper computation (because it scales up to more electrons less steeply than conventional methods that include some electron correlation). Several approximate functionals of the electron density are in common use and are relatively successful in prediction of molecular structure, and are known to yield geometries and energies of at least MP2 quality. The difficulties of calculating magnetic response properties using DFT arise in two major ways. The first is intrinsic to all DFT methods, because only approximate functionals are available and they are deficient in various ways. NMR parameters show up these deficiencies most glaringly because of their...
extreme sensitivity to the electron distribution in the immediate vicinity of the nucleus. Second, is that in the presence of a vector potential (when magnetic fields or magnetic moments are present) the functionals of both the current density and the electron density are needed, thus a current density functional theory (CDFT) is the appropriate theory. A current-dependent DFT has been derived by Vignale et al.\(^{35-37}\) Handy et al. have used this approach.\(^{38}\) On the other hand, more commonly, a generalization of the Kohn–Sham density functional theory (KSDFT) has been used to obtain magnetic responses using only the functional of the electron density; the current density part of the calculation is not included. This is by far the most commonly used calculation method. It remained to be shown by Grayce and Harris\(^{39,40}\) that when the magnetic field is produced by a constant applied field and a single nuclear magnetic dipole, the current density is a functional of the electron density. Furthermore, they showed that in the linear response regime, the current density functional depends on the zero field electron density. As a consequence, magnetic responses in the linear regime are solely functionals of the electron density in the absence of a magnetic field. Grayce Harris call this the magnetic field density functional theory (BDFT).\(^{39,40}\) The problem is that in all DFT approaches, only approximate functionals are yet available, and the magnetic response DFT approaches, whether CDFT or KSDFT or BDF, all suffer from this same difficulty.

There are several independent formulations of DFT of shielding. A large number of DFT calculations have been carried out by Malkin, Salahub et al. without including the effects of the current density, using a local density approximation (LDA) in a SOS method and IGLO method of local origins for shielding tensor calculations.\(^{41,42}\)

In the CDFT of Vignale et al., in addition to the usual exchange correlation functionals of the density that are used for solving electronic structure problems in the absence of a magnetic field, the effects of a current density are included.\(^{35-37}\) Van Wullen has derived the coupled perturbation equations for calculating nuclear magnetic shielding tensors using CDFT in both the IGLO and the GIAO method of introducing local gauge origins.\(^{43}\) Lee, Handy, and Colwell derived equations within the Kohn–Sham formulation of DFT for calculations of nuclear magnetic shielding tensors with GIAO basis functions using CDFT, including the use of a local exchange correlation functional which depends on both the electron density and the paramagnetic current density.\(^{38}\) To put the various DFT formalisms and calculations in context they applied their working expressions to the systems HF, N\(_2\), CO, F\(_2\), and H\(_2\)O. By doing computations using conventional atomic basis functions versus GIAOs basis functions, using various local functionals of the density in popular use, such as the exchange functional of Becke with the correlation functional of Becke–Lee–Yang–Parr (BLYP) and others, with and without including the current-dependent functional proposed by Vignale, Rasolt, and Geldart,\(^{37}\) with or without the ad hoc correction of Malkin et al.\(^{41}\) Lee et al.\(^{38}\) provide some very useful comparisons. They of course found what is already well known, that using GIAOs leads to better results than using conventional (gaugeless) atomic basis functions employing CHF or any DFT method. They found that including the current-dependent functional proposed by Vignale, Rasolt, and Geldart\(^{37}\) gives only small corrections. They also established that DFT and CDFT methods exhibit general difficulty in describing multiply bonded systems such as N\(_2\) and CO. An important observation is that calculations using local functionals of the density give severely deficient eigenvalues. To overcome this, a more accurate functional must be developed. Since the Malkin correction is to modify the energy denominators, this has the effect of shifting the incorrect eigenvalues already noted above. Indeed, direct comparisons by Lee et al. using various functionals with and without the ad hoc Malkin correction lead to a significant improvement in the CO case. They also found that, unlike in the HF molecule, exchange terms are significant in the CO molecule and the current-density terms are no longer negligibly small. The general conclusions are that the use of local density functionals is a major deficiency and overwhelms the small current density corrections.\(^{38}\) The best results for CO in the Lee et al. formulation of CDFT/GIAO appear to come from the hybrid B3LYP functional\(^{44,45}\) combined with the Malkin correction.\(^{41}\) Thus, in spite of what appears to be a lack of solid theoretical foundation, the ad hoc Malkin correction gives very promising results.

There are several other implementations of DFT in shielding calculations, all of which use only current-independent exchange correlation functionals: the IGLO-based DFT of Malkin and Salahub already mentioned and the GIAO-based DFT calculations introduced by Schreckenbach and Ziegler,\(^{46,47}\) Pulay et al.\(^{48}\) and Cheeseman, Trucks, Keith, and Frisch\(^{49}\).

In practice, the calculations in the Ziegler DFT/GIAO implementation employ Slater-type orbitals as atomic basis functions (unlike most computations which use Gaussian-type basis functions).\(^{46,47}\) They have also used the frozen core approximation in some systems.\(^{50}\) Pulay et al. have developed a DFT/GIAO based on their program system which uses analytic derivative theory (TX90).\(^{48}\) They derive their DFT/GIAO equations in the density matrix formulation used originally.\(^{48}\) Compared to the Hartree–Fock case, the only new quantity is the first-order exchange correlation term. In the Pulay implementation, these terms are evaluated by the same Becke
The DFT method has severe limitations for the calculations of spin–spin coupling which are connected to the inability of the presently available exchange correlation functionals (LDA and general gradient approximation) to produce the highly accurate spin densities required to describe properly the FC term for molecules containing atoms lying at the right of the periodic table and containing lone pairs. The $J^{(SD)}$ contribution is the most time-consuming and is usually neglected in DFT calculations of $J$ because it is usually smaller than the error in the $J^{(FC)}$ calculation by this method. Improved results will require a better exchange correlation functional to describe the spin polarization more precisely. A parameterized functional trained to reproduce a set of gas phase isotropic hyperfine coupling constants in nonsinglet radicals would be a good start.

2.6 Relativistic Calculations

It is well known that relativistic effects are very important in the study of heavy elements. Instead of the Schrödinger equation one has to solve a many electron generalization of the four-component Dirac equation. Fully relativistic calculations are very time-consuming even at the SCF level. Other approaches are based on perturbation theory, starting from a nonrelativistic calculation as zeroth-order approximation. A direct perturbation theory formalism has been proposed by Kutzelnigg in 1990 and recently he and his co-workers have laid out the formalism for stationary direct perturbation theory which is conceptually strictly equivalent to a theory in terms of four-component spinors, but operationally on a two-component or even one-component level, and yet avoiding the singularities that arise in using other approaches. The formulation is a relativistic Hartree–Fock theory for closed shell states describable by a single Slater determinant. The eagerly awaited next step is yet in progress, application of multiple perturbation theory formalism to treat relativistic effects on molecular properties such as shielding. Meanwhile, present relativistic calculations of nuclear magnetic shielding are still very approximate.

The relativistic effects on shielding may be considered in three parts. One is the direct effect of the relativistic contraction of $s$ and $p$ inner shells and the relativistic SCF expansion of $d$ and $f$ shells on the diamagnetic contribution. The contraction of the $s$ and $p$ shells leads to larger values of $(r_i N^{-1})$ and $(r_i N^{-1})$. The essentially constant relativistic effect on the diamagnetic contribution numerical integration scheme they use for the exchange matrix elements themselves. Although in principle this method is identical to that of Schreckenbach and Ziegler, there are major differences in implementation. First they use Gaussian basis functions rather than Slater basis functions. Second, the Pulay implementation does not use fitting functions for the Coulomb and exchange functions. Rather they calculate the Coulomb term exactly, using traditional two-electron integral evaluation, and calculate exchange correlation terms by the numerical integration technique of Becke. Independently, Cheeseman et al. presented their formulation of the DFT/GIAO method and also DFT/CSGT (Continuous set of gauge transformations) (or IGAIM). The latter makes use of the highly successful IGAIM and the more general CSGT method of Keith and Bader (wherein the current is determined through the definition of a CSGT, a separate gauge origin to calculate the current $J^{(r)}$ at each point $r$ in real space). They found the IGAIM results essentially identical to the CSGT. Cheeseman et al. compared the results from the DFT methods with CHF/GIAO and CHF/CSGT calculations of isotropic nuclear magnetic shielding of $^{13}$C in a large number of molecules.

How well does DFT predict absolute shielding? DFT accounts for correlation effects implicitly in the exchange correlation functionals used and thus might be expected to give superior results in comparison to CHF calculations for a given GIAO set of basis functions, in those molecules such as CO, N$_2$, NNO, HCN where electron correlation effects on shielding are important. Absolute shieldings obtained using the gradient-corrected functionals are consistently better than CHF in these molecules, although the improvement is small in some cases. Using a basis set which is sufficient to predict accurate shifts using GIAO/MP2 theory, various DFT functionals consistently predict chemical shifts that are too deshielded compared with experiment. The absolute shielding results are too deshielded by 10–20 ppm for $^{13}$C, by 6–40 ppm for $^{15}$N, and by 30–40 ppm for $^{17}$O in the selected molecules where the absolute shielding results were known. Anisotropies are even worse. The isotropic chemical shifts correlate better with experiment, with somewhat smaller average standard deviation in the DFT results in comparison with experiment compared to CHF using GIAOs. The test of any theoretical method for calculating $\sigma$ is the comparison of the results with the benchmark CCSD(T) calculations of Gauss for a set of small molecules at the same fixed geometries. The successful wide applicability of the DFT method for calculating $\sigma$ lies in its applications to molecules with large numbers of electrons, where the accurate CCSD(T) calculations are not feasible and even MP2 level calculations are prohibitively expensive and impractical.
coming from the core electrons can be a large correction but hardly changes as the atom is compared from one molecule to the next. This is of little concern in taking differences, the chemical shifts. Another relativistic effect is the indirect effect of this s and p contraction and d and f expansion within the Hartree–Fock scheme, an effect that varies from one molecule to the next. Both of these relativistic effects are “spin-free” in nature. Third is the effect of introducing the spin–orbit terms. To calculate the additional contributions to the nuclear magnetic shielding associated with spin–orbit interactions, the latter has been approached approximately by a nonrelativistic treatment with the spin–orbit operator added on as a perturbation. These corrections can be large for nuclei whose immediate neighbors are atoms that have large values of spin–orbit coupling constants, e.g. the heavier halogens. Both the spin-free relativistic term and the spin–orbit terms can be important and they can couple with each other, as they do in $^{199}$Hg shielding in mercury halides.\(^{(54)}\) One way of approximately including relativistic effects is to use relativistic effective core potentials. Nakatsuji et al. have introduced this and other additional approximations.\(^{(55)}\) The so-called normal halogen dependence of chemical shifts (increasing shielding upon substitution of neighboring atoms by Cl, Br, I, in that order) which had previously been attributed to relativistic effects,\(^{(56)}\) has been accounted for entirely by the spin–orbit contributions centered on the halogen atoms in approximate calculations of shielding of $^1$H, $^{13}$C, $^{29}$Si, $^{71}$Ga, and $^{115}$In nuclei in the respective halides.\(^{(55,57,58)}\)

These approximate calculations have established the importance of the spin–orbit terms for shielding of nuclei having Cl, Br and I neighbors. However, calculations of heavy atom shielding are not yet on a sound footing at the level of relativistic theory used here. Furthermore, the number of electrons involved is very large and basis sets used are far from saturated so that it is not yet possible to have good nonrelativistic baseline values against which it may be possible to judge quantitatively that the relativistic approximations used are bridging the gap between nonrelativistic calculations and experiment. When a robust method is used which is consistent in the level of inverse powers of the speed of light used for each term, as is promised by the Kutzelnigg approach,\(^{(53,59)}\) for example, coupled with a serious basis set study, this problem will be more rigorously addressed. The second problem which is just as important is the lack of experimental absolute shielding data in the gas phase for such heavy nuclei. This leads to comparisons of theoretical values with solution data where solvent effects may even bring some doubt as to the actual chemical species being observed. The problem is particularly severe with the calculations involving bare anions of In, for example, rather than neutral species.

The spin–spin coupling is itself a purely relativistic phenomenon. However, starting from a relativistic Hamiltonian such as the Dirac–Coulomb–Breit Hamiltonian, and neglecting the small components of the four component functions, the expressions for the spin–spin coupling tensor in the nonrelativistic limit can be derived.\(^{(57)}\) Relativistic formulations of $J$ have been derived. Aucar and Oddershede have formulated a fully relativistic ab initio theory of the spin–spin coupling in its most general form within the polarization propagator approach.\(^{(60)}\) They neglect the Breit interaction to derive the formulas which look very much like the nonrelativistic expression for spin–spin coupling in the propagator approach, except that the elements involve integrals of the full four component wavefunctions. The large component of the relativistic wavefunction is the nonrelativistic wavefunction. One relativistic expression replaces the nonrelativistic $J^{(0P)}$, $J^{(SD)}$, and $J^{(FC)}$ terms. Ramsey’s nonrelativistic expressions are obtained in the limit that the speed of light goes to infinity. Kutzelnigg has also developed a relativistic theory of spin–spin coupling.\(^{(59)}\) Earlier, Pyykkö derived a relativistic analog to Ramsey’s theory, using a relativistic nuclear Zeeman hyperfine Hamiltonian as a perturbation.\(^{(11)}\) Implementation of Pyykkö’s theory has been limited to one-bond couplings.\(^{(61)}\)

### 3 CALCULATIONS OF NUCLEAR MAGNETIC RESONANCE CHEMICAL SHIFTS

#### 3.1 Comparison of Various Computational Methods Using the Same Set of Test Molecules

Which method would be best to use for calculating NMR chemical shifts? The answer depends on the question being asked. Is the chemical shift to be used to discriminate between two or more proposed chemical structures? Is the goal to verify a particular structure? Is it to determine if the molecule is fluxional or not, if forming a complex or not, on the basis of the NMR chemical shifts? Is it to assign the multitude of peaks observed in a crystalline sample? Sometimes we just want to understand what it is about the electronic structure that gives rise to an observed chemical shift or its temperature dependence. Depending on the accuracy that is required to answer the question being asked, a particular method and level of calculation and a particular size of basis set may be sufficient. It is not always necessary to use the most accurate method and the largest basis set. But first, we will compare methods across the board, using several benchmark molecules, in order to see the level of accuracy that may be expected.
We present some comparisons of absolute isotropic shieldings calculated using GIAOs in Tables 1 and 2. The calculations are for a fixed geometry, and therefore should be controlled at the zero-pressure limit. They correspond to the chemical shift for an isolated molecule. The error bars are associated with the determination of the absolute scale based on spin rotation constants for specific systems. The magnitude of the triplet excitations are small, amounting to less than 1 ppm. MBPT(4), CCSD and MCSCF all provide an adequate treatment of electron correlation effects for these simple systems. Furthermore, the agreement with experiment is very good. It has been suggested that these calculations are good enough to be able to say that the $^{17}$O shielding scale (which has an error bar of ±17.2 ppm) may actually be closer to the less shielded edge of the error limits. It has been found in systematic studies of a large number of $^{13}$C chemical shifts that MBPT(2)-level results are much closer to experiment than CCSD results. It appears that MBPT(2) benefits from a fortuitous but consistent error cancellation, while CCSD (which is theoretically more complete and is in principle a more reliable approach) does not. Triple excitation effects are considerably more important for the multiply bonded systems CO, N$_2$ and HCN. The magnitude of the triple excitation corrections (2–6 ppm) for these systems leads to calculated results that are closer to experiment. For the F$_2$ molecule, inclusion of triple excitation corrections

Examination of Tables 1 and 2 permit the following conclusions. For the hydrides HF, H$_2$O, NH$_3$ and CH$_4$, electron correlation effects described by triple excitations are small, amounting to less than 1 ppm for the nonhydrogen nuclei. The effects for proton shieldings are not shown in the tables, but they are even smaller, of the order of 0.1 ppm. MBPT(4), CCSD and MCSCF all provide an adequate treatment of electron correlation effects for these simple systems. Furthermore, the agreement with experiment is very good. It has been suggested that these calculations are good enough to be able to say that the $^{17}$O shielding scale (which has an error bar of ±17.2 ppm) may actually be closer to the less shielded edge of the error limits. It has been found in systematic studies of a large number of $^{13}$C chemical shifts that MBPT(2)-level results are much closer to experiment than CCSD results. It appears that MBPT(2) benefits from a fortuitous but consistent error cancellation, while CCSD (which is theoretically more complete and is in principle a more reliable approach) does not. Triple excitation effects are considerably more important for the multiply bonded systems CO, N$_2$ and HCN. The magnitude of the triple excitation corrections (2–6 ppm) for these systems leads to calculated results that are closer to experiment. For the F$_2$ molecule, inclusion of triple excitation corrections

The benchmark test molecules shown in Tables 1 and 2 are isotropic averages in the gas at the zero-pressure limit. They correspond to the thermal average for an isolated molecule. The error bars are associated with the determination of the absolute scale based on spin rotation constants for specific molecules (the CO molecule for $^{13}$C, NH$_3$ for $^{15}$N).

The estimates of the vibrational corrections have been subtracted from $\sigma_0$ to obtain the value $\sigma_1$ (the value for a rigid isolated molecule at its equilibrium molecular geometry) with which calculations are to be compared. See Jameson$^{(62)}$ for the references for experimental data and vibrational corrections.

The benchmark test molecules shown in Tables 1 and 2, except for CH$_4$, are specifically chosen as examples that presented problems of electron correlation, especially in $^{15}$N, $^{17}$O, and $^{19}$F shielding. Observe in Tables 1 and 2 the slow convergence in some molecules, faster in others, of the series SCF, MBPT(2), MBPT(3), MBPT(4). Observe also the consistent improvement over SCF afforded by the approximate exchange correlation functionals used in DFT calculations especially for CO, N$_2$, HCN. Observe also how close CCSD(T) results come to the FCI (in BH molecule). More typical of the applications of calculated NMR chemical shifts to analysis of mixtures are calculations of $^{13}$C chemical shifts. Table 3 demonstrates the importance of electron correlation to $^{13}$C chemical shifts in the comparison with chemical shifts in the gas phase at the low density limit. It can be seen that the second-order electron correlation generally brings the calculations close enough to experiment to be useful for analysis.

### 3.2 Comparison of Carbon Chemical Shift Tensor Components with Calculations

A more stringent test of the calculations has to do with reproducing the elements of the shielding tensor, not just the isotropic average that is obtained in solution or in a MAS experiment in the solid state. In a single crystal study of a sugar, for example, there are a large number of peaks which have to be assigned in order to verify the structure. Complete assignment of $^{13}$C shielding tensors in the entire molecule from single crystal studies has leads to a change of about 15 ppm and brings the calculated value closer to experiment. Results for F$_2$ at lower levels of calculation do not provide satisfactory agreement with experiment. Except for the F$_2$ molecule, GIAO/MCSCF calculations using very large active spaces (only those are shown in Tables 1 and 2) provide results comparable to CCSD. It has been found, and is obvious in Tables 1 and 2, that the DFT method consistently overestimates the paramagnetic term leading to too much deshielding for these benchmark molecules. The SCF value is good enough for CH$_4$, NH$_3$, and HF molecules to agree reasonably with the thermal average value (since the neglect of electron correlation effects in these and most molecules is compensated for by the neglect of rovibrational averaging), whereas this level of theory is clearly inadequate for the multiply bonded CO, HCN, and N$_2$, and also for H$_2$O and F$_2$.

The benchmark test molecules shown in Tables 1 and 2, except for CH$_4$, are specifically chosen as examples that presented problems of electron correlation, especially in $^{13}$N, $^{17}$O, and $^{19}$F shielding. Observe in Tables 1 and 2 the slow convergence in some molecules, faster in others, of the series SCF, MBPT(2), MBPT(3), MBPT(4). Observe also the consistent improvement over SCF afforded by the approximate exchange correlation functionals used in DFT calculations especially for CO, N$_2$, HCN. Observe also how close CCSD(T) results come to the FCI (in BH molecule). More typical of the applications of calculated NMR chemical shifts to analysis of mixtures are calculations of $^{13}$C chemical shifts. Table 3 demonstrates the importance of electron correlation to $^{13}$C chemical shifts in the comparison with chemical shifts in the gas phase at the low density limit. It can be seen that the second-order electron correlation generally brings the calculations close enough to experiment to be useful for analysis.

A more stringent test of the calculations has to do with reproducing the elements of the shielding tensor, not just the isotropic average that is obtained in solution or in a MAS experiment in the solid state. In a single crystal study of a sugar, for example, there are a large number of peaks which have to be assigned in order to verify the structure. Complete assignment of $^{13}$C shielding tensors in the entire molecule from single crystal studies has...

$^a$ Gauss.$^{(56)}$

$^b$ Jameson and Jameson.$^{(65)}$

been developed to the highest level by Grant et al. The multiple axis sample reorientation mechanism developed in this group permits the study of crystals containing 50–100 magnetically different nuclei per unit cell. In a polycrystalline solid with a very large number of distinct $^{13}$C chemical sites, it is possible, using multidimensional NMR techniques to obtain the individual shielding tensor elements for each isotropic peak in the MAS NMR spectrum. To assign all these, ab initio calculations of shielding tensor elements are indispensable.

How well do calculations predict the tensor elements? It is important to be able to do these calculations in a relatively routine manner (one cannot use CCSD level of calculations) so that fitting to the observed spectra can be done expeditiously. Otherwise, theoretical calculations would not be practically useful for analysis. The group of D.M. Grant has carried out the largest number of such analyses.$^{(66)}$ Single crystal NMR experiments produce a complete description of the shielding tensor with six independent components specifying the tensor in a fixed crystallographic coordinate system (the so-called icosahedral tensor representation). Figure 1 shows the degree of success of SCF level calculations using a modest size basis set.$^{(67)}$ The high level of agreement between calculated and experimental tensors for $^{13}$C is such that only the structural parameters (bond distances and angles) limit the level of agreement. This means that ab initio calculations and measurements together can be used to address certain fine details of solid-state structure, surpassing the accuracy of X-ray data.$^{(68)}$ This is possible because the shielding tensor is exquisitely sensitive to bond distances.

It is quite important to be able to predict theoretically the individual tensor components of the building blocks of proteins, in order to establish that it is possible to use NMR chemical shifts in the determination of protein structure. In Figure 2 is the demonstration of the degree of success of SCF level calculations using a modest basis set for the tensor elements of $^{13}$C in a single crystal of threonine.$^{(69)}$

3.3 Other First Row Nuclei

A systematic study of B, N, O, and F shielding using the IGLO method of distributed origins provides a measure of the initial successes of theoretical calculations for these nuclei in systems of known structure.$^{(70)}$ $^{11}$B NMR chemical shift calculations have been used for the analyses of new boron compounds, which are particularly useful when more than one structure can fit the electron diffraction data. Shielding calculations for N, O, and F in most molecules do require a theoretical treatment including electron correlation. Ab initio calculations for...
Experimental chemical shifts observed in solution, however, the calculations were not validated against any of the available absolute shielding, such as in CIF (\(\sigma = -516 \pm 23\) ppm) or HCl (\(\sigma = 952\) ppm). GIAO calculations including second-order MP2 level electron correlation for \(^{31}\)P has been used to estimate the infinite-order results, and these agree very well with the absolute shieldings that are known for molecules ranging from PN to P\(_4\) a range of about 900 ppm.

### 3.5 Other Heavy Nuclei

Heavy nuclei present some general problems for calculations of NMR shielding. First, the larger number of electrons requires larger numbers of basis functions and including electron correlation becomes very expensive. Second, relativistic effects could be important. Third, in some cases there are few if any gas-phase data that can be used to test the absolute shieldings from the calculations; in many cases, only solution-phase experimental data is available for comparison with calculations (e.g. \(^{69}\)Ga, \(^{115}\)In, \(^{72}\)As, \(^{121}\)Sb, \(^{130}\)Xe). \(^{77}\)Se is an exception to this third difficulty and can be used to explore the range of problems associated with heavy nuclei in general.

Correlation effects must be included for a quantitative description of \(^{77}\)Se chemical shifts in those same bonding situations where \(^{17}\)O shielding has been found to require correction for correlation effects. The additional complication of the large number of electrons therefore makes the \(^{77}\)Se calculations more challenging. The results of ab initio calculations are very good. At the SCF level, for example, various calculations for the isotropic shielding of H\(_2\)Se lead to 2167.6, 2170, and 2171 ppm, which are very close to each other and reasonably close to the value calculated at the CCSD level (2213 ppm) and the experimental value: 2101 ± 64 ppm on the absolute shielding scale without the relativistic corrections for the diamagnetic shielding of the free atom. The electron correlation effects are only 2% of the total shielding in H\(_2\)Se and O=C=Se; they are 7% of the total shielding in Se=C=Se. This is very encouraging. Table 4 shows only the highest level ab initio calculations compared with DFT calculations and experiment. Keeping in mind that the rovibrational corrections are about –60 ppm, (that is, \(\sigma_i\) may be converted into experimental \(\sigma_i\) by adding –60 ppm) the CCSD values are within 3–5% of the experimental values. The DFT results are less shielded than the CCSD values by 100–200 ppm.

The situation for \(^{125}\)Te is comparable to that in \(^{77}\)Se. \(^{125}\)Te in TeF\(_6\) gas has an absolute shielding of 2570 ± 130 ppm in the zero density limit, if the nonrelativistic diamagnetic shielding of the free atom is used. The DFT nonrelativistic calculations give 2260 ppm, which is 200–300 ppm less shielded. This is in the same direction as the relativistic calculations for \(^{125}\)Te.
as the difference between DFT and CCSD in the $^{77}$Se case. The ability of DFT calculations to reproduce the full range of $^{125}$Te chemical shifts in all types of chemical bonding situation is very encouraging.\(^{(78)}\)

### 3.6 Transition Metal Nuclei

For transition and post-transition metal nuclei there are the usual problems associated with heavy nuclei, plus the lack of absolute shielding information. With one exception, there are no gas-phase data to establish absolute shielding scales. Despite these problems some DFT calculations have been done for $^{103}$Rh, $^{91}$Zr, $^{57}$Fe- and $^{59}$Co by Bühl and others. A relativistic formulation in which spin orbit contributions are neglected, resulting in the so-called scalar relativistic method, is being explored within the DFT/GIAO method.\(^{(79)}\) In calculations for other transition and post-transition metal nuclei for which the absolute shielding is not known, only shielding differences, i.e. chemical shifts, have been used to compare with experiment. The agreement is not yet at the level that is achievable routinely with $^{13}$C shielding calculations. The range of transition metal shifts is usually very large and these exhibit useful diagnostic variations with ligand types. The theoretical calculations have yet to catch up with experiment. Witness, for example, the one case where gas-phase data are available: CdMe$_2$ molecule. Beam measurements show neat CdMe$_2$ liquid being deshielded by 1746 ppm from the free Cd atom, which has an absolute shielding of 4813 ppm.

Thus $\sigma = 3067$ ppm for neat CdMe$_2$ liquid at room temperature. The gas is found to be 62.1 ppm unusually less shielded than the neat liquid,\(^{(80)}\) so that $\sigma = 3005$ ppm for gaseous CdMe$_2$ at 97°C. This is to be compared with 3504.5 ppm (too shielded by 500 ppm) from GIAO Cd shielding calculations on an isolated molecule of CdMe$_2$ with a spread of 105 ppm depending on basis set used, neglecting relativistic corrections or electron correlation.\(^{(81)}\) Other calculations give more shielded values than this, as much as 900 ppm more shielded than 3005 ppm. Since the chemical shift range of Cd is about 900 ppm, the level of accuracy needs considerable improvement.

### 4 CALCULATIONS OF SPIN–SPIN COUPLING CONSTANTS

The various mechanisms in the nonrelativistic limit, given by Equations (10–14) are $J^{(OD)}$, $J^{(OP)}$, $J^{(FC)}$, $J^{(SD)}$, and the cross-term $J^{(SDFC)}$ which has no isotropic part. The OD term, $J^{(OD)}$, is the only term that is not expressed as a SOS in the Ramsey formulation, rather it is an average value of an operator containing two nuclear spins. $J^{(OD)}$ is not usually small and can be rather large for $^2J(\text{HH})$. A systematic study of this term shows that it is not very sensitive to basis set choice (double zeta with polarizations functions are sufficient) and to inclusion of electronic correlation (SCF average values will do); it is particularly important for $^nJ(\text{HH})$, independent of $n$.\(^{(82)}\) The sign of the contribution is negative for two-bond HH coupling. From a systematic study of the OP mechanism using DFT, $J^{(OP)}$ appears to be significant for most couplings although not dominant, and is particularly important for couplings involving a nucleus with lone pairs.\(^{(83)}\) The sign of the contribution (reduced so as to not include the nuclear gamma values) can be positive or negative; $J^{(OP)}$ is negative and is the largest contribution for CO and N$_2$ molecules, for example. The SD term $J^{(SD)}$ is the most time-consuming to calculate and so is sometimes neglected; it is not small when multiple bonds are involved between the coupled nuclei. For example, for N$_2$ molecule it is comparable to and partly cancels the $J^{(FC)}$ term.\(^{(25,27,84)}\) Electron correlation is very important for multiple bonded systems and must be accounted for to obtain reliable results: results at the RPA level have the wrong sign and magnitudes for coupling in both CO and N$_2$ molecules. The sign and magnitude of the FC, $J^{(FC)}$, term varies across the periodic table. Where no multiple bonds are involved, this mechanism usually provides the largest contribution to one-bond coupling constants. Electron correlation is very important for this mechanism and unrealistic values may result from calculations at the RPA level.

#### 4.1 One-bond Coupling Constants

Table 5 shows the various contributions to the one-bond couplings in HF, HCl, CO, and N$_2$. The uncorrelated

results (RPA) are shown to be inadequate. Various methods of including electron correlation are (1) through the polarization propagator approach to SOPPA and CCSD level, (2) MBPT, (3) MCLR theory, (4) DFT, and (5) EOM/CCSD. The DFT calculations suffer from the inadequacy of the approximate exchange correlation functionals available. These functionals may be good enough to reproduce binding energies, but offer less accurate descriptions of the electron spin distributions where they are needed in calculations of $J$, especially the FC mechanism. MCLR theory uses an MCSCF reference state and is capable of describing electronic systems with large static correlation effects.

How well do calculations predict the simple one-bond $^1J(CH)$? This may be observed in Table 6, where it is seen that the isotropic value is entirely dominated by the FC mechanism and is easily reproduced by calculations that include correlation, including DFT. Correlation effects can be substantial. For example, the uncorrelated calculation of the term FC for $^1J(CH)$ in HCCH molecule leads to 449.3 Hz, whereas SOPPA which includes correlation up to second order gives

246.5 Hz, which agrees quite well with the experimental value of 248.7 Hz.

On the other hand, calculations are less successful with the one-bond J(CF). DFT is found to underestimate the FC contribution to the one-bond coupling because of the inability of such exchange correlation functionals to produce the accurate spin densities required for this calculation. In the presence of polarizable lone pairs the correlation problem is more severe, and the available functionals do not describe the spin densities well enough in the case of J(CF) which are predicted to be about 110 Hz away from experimental values, as shown in Table 7.

There are many interesting trends observed in coupling constants, in signs, magnitudes, dependence on substituents, stereochemistry, position of coupled nuclei in the periodic table, and so on. Many of these trends have been very useful in analysis of spectra and yet a sound theoretical basis for few of such trends has been established.

The anisotropy of the tensors calculated with and without electron correlation are shown in Table 8 for HF and HCl. First of all, note that the FC mechanism is purely isotropic and the cross-term J(SD/FC) which has no isotropic part, is responsible for a large part of the total anisotropy of the tensor. The anisotropy of the orbital mechanisms are opposite in sign and partly canceling. The contribution to the anisotropy from the SD mechanism is small. Any anisotropy observed in the J tensor in oriented molecules has to come from the mechanisms other than the FC term. However, because of the very large contribution from the cross-term J(SD/FC) to the anisotropy (78% in HF and 93% in HCl), the magnitude of the measured anisotropy unfortunately conveys very little information about the magnitude of the contributions of mechanisms other than the FC term to the isotropic average observed in solution. The effect of electron correlation on the individual components of J(OD) is small. (It is well known that the effect of correlation on the isotropic average of J(OD) is small and that it is not very sensitive to basis set choice.) The orbital mechanisms have opposite contributions to the anisotropy, J(OD) and J(OP) are similar in sign (positive) and magnitude (large), and so are J(OP) and J(OD) (negative and smaller). The effect of electron correlation on the cross-term J(SD/FC) is about 5%. If this is typical, uncorrelated calculations should permit estimation of the J anisotropy that may be expected in oriented systems. There are only a few measurements of the anisotropy of the J tensor because the observable quantity in solids is the (D + J) tensor, and the direct dipolar coupling tensor D overwhelms the sum. The anisotropy of the J tensor has been determined in a few favorable cases, such as 1J(31P–X), where X = ¹⁰⁹Hg, ¹⁹⁵Pt, ¹¹⁵In, in Wasylishen’s laboratory. A typical such measurement in a single crystal of a mercury phosphine complex shows the experimental technique for arriving at J = 11800 Hz, J = 6400 Hz, and the isotropic value is 8200 Hz. While the isotropic value is very likely to be dominated by the FC mechanism, the

ₚ Fukui et al. (86)
anisotropy $\Delta J = 5400$ Hz comes entirely from the non-FC mechanisms.\(^{(92)}\)

### 4.2 The Two-bond Coupling Constant

The geminal coupling constant \(2J(HH)\) turns out to be very difficult to predict. As is the case for all \(2J(HH)\), the \(J^{(OD)}\) term is important. So also is the \(J^{(OP)}\) term, but it has the opposite sign to the \(J^{(OD)}\) term. For the series CH\(_4\), SiH\(_4\), GeH\(_4\), SnH\(_4\), the orbital mechanism \(J^{(OD)}\) and \(J^{(OP)}\) terms have opposite signs and they very nearly cancel in CH\(_4\). The magnitude of the \(J^{(FC)}\) term varies from large negative to large positive. There is poor agreement of the total calculated value with experiment.\(^{(31)}\) The experimental variation of \(2J(HH)\) with the nature of the intervening atom is not predicted quantitatively, although the trend of algebraically increasing from C to Sn is reproduced at every level of correlation treatment.\(^{(31,52)}\) In the series CH\(_4\), NH\(_3\), OH\(_2\), \(2J(HH)\) has the sign of the \(J^{(FC)}\) term, but is by no means dominated by it. Here too, the experimental variation of \(2J(HH)\) with the position of the intervening atom in the periodic table is not predicted quantitatively, although the trend of algebraically increasing from C to N to O is reproduced at every level of correlation treatment.\(^{(27)}\)

### 4.3 Coupling Over Three Bonds

From a practical viewpoint, one of the very early major successes of theoretical calculations of spin–spin couplings is the prediction of the torsion angle dependence of \(3J(HCCH)\), known as the Karplus equation. The very simple valence bond calculation\(^{(97)}\) using a small four-atom fragment (HCCH) led to an unequivocal prediction which permitted a practical determination of structure strictly from the observed isotropic value of the coupling constant. It was found later that the dihedral angle dependence of the three-bond coupling is general and Karplus-type equations have been used to describe many types of three-bond coupling pathways, for example \(3J(X-Y-C-H)\), where X represents other nuclei such as \(^{31}\)P or \(^{13}\)C or \(^{15}\)N, and three-bond coupling paths such as PtCCC, PWNN, PCPSe, etc. Used with caution, experimental \(3J\) values and a Karplus equation make a reasonable conformational probe. The original Karplus equation is written in the form of Equation (19)

\[
3J(HCCH) = C_0 + C_1 \cos \phi + C_2 \cos(2\phi) \tag{19}
\]

with \(C_0 = 8.02\), \(C_1 = -1.2\), and \(C_2 = 7.0\) Hz as the empirical parameters, although other forms have also been used. The coefficients in the above equation have been calculated by various methods using ethane as the model. The \(J^{(FC)}\) contribution is the largest and \(J^{(SD)}\) the smallest. One such calculation, with second-order correlation for all contributions except the FC contribution (which was done with third-order correlation), leads to \(C_0 = 4.66\), \(C_1 = 0.39\), and \(C_2 = 5.78\) Hz.\(^{(94)}\) In the general case, the \(3J\) value also depends on the bond angles between any two adjacent bonds out of the three, and there are substituent effects.

### 4.4 Relativistic Effects

Why are relativistic effects important for spin–spin couplings of heavy nuclei? Relativistic effects are particularly important for electronic properties which depend on the electronic wavefunctions very near nuclei where electrons move fast. Relativistic effects on the electronic structure of atoms and molecules consist of a contraction of s and p shells, the spin–orbit splitting of the non-s shells, and the relativistic SCF expansion of d and f shells. The contraction of the s and p shells leads to larger spin densities at the nuclei (FC term) and also larger values of \(I_{nN}^{(-3)}\) (other mechanisms). An a posteriori correction of the nonrelativistic values of these by a multiplicative factor \(B(n, Z)\), depending on the principal quantum number \(n\) and the nuclear charge \(Z\), was suggested by Breit in 1930\(^{(95)}\) and this multiplicative factor has been used by Pyykö and others to impose a simple relativistic correction on the values of \(J\) calculated using the nonrelativistic formulas.\(^{(96)}\) This factor, \(B(n, Z)\), is 1.348 for the \(n = 5\) shell of Sn and is 2.592 for the \(n = 6\) shell of Pb.\(^{(96)}\) That is, the nonrelativistic calculations underestimate the value of \(J(SnH)\) by a factor of 1.348. When both nuclei involved in the coupling are heavy, the product of two such factors is substantial.

### 5 CALCULATIONS OF ELECTRIC FIELD GRADIENTS

#### 5.1 Electric Field Gradient Tensor Versus Electronic Structure in the Solid State

The electric field gradient tensor is intimately related to the local molecular structure. In crystalline silicates, for example, the measured \(^{17}\)O nuclear quadrupole coupling constant serves as a probe of oxygen coordination number and geometry. Using experimental correlations between structure (Si–O–Si bond angles, for example) in crystalline silicates and the measured \(^{17}\)O quadrupolar coupling constants, the Si–O–Si bond angle distribution in silicate glasses can be deduced, bridging and nonbridging oxygens can be distinguished.\(^{(97)}\) Electric field gradient tensors of deuterium nuclei in hydrogen bonded positions, such as the amide or carboxy hydrogen in peptides, give deuteron/proton bond directions with an accuracy rivaled only by neutron diffraction, since it has been established that the unique eigenvector of a deuteron quadrupole
coupling tensor is approximately parallel to the bond direction of the deuteron.\(^\text{98}\)

### 5.2 Calculations of Electric Field Gradients at Nuclei in Isolated Small Molecules

The most reliable method of obtaining the intrinsic electric quadrupole moment of a nucleus is by very high quality ab initio calculations of the electric field gradient tensor in selected small molecules in which the nuclear quadrupole couplings of the nucleus have been measured accurately via microwave spectroscopy. The value of \(eQ\) is obtained as a fit parameter.\(^\text{99}\) Once calibrated, this \(eQ\) value can be used to deduce from experiment the electric field gradient tensor for any other nuclear site.

Accurate theoretical calculations of electric field gradients for small molecules pose no special problems; requirements of basis set quality and appropriate level of electron correlation depend on the molecule, just as for calculations of shielding, but less demanding in that only the ground electronic wavefunction is required. Just as for shielding calculations, the \(r^{-3}\) factor in the electric field gradient requires wavefunctions that are accurate in the immediate vicinity of the nucleus.

### 5.3 Simulations of Nuclear Quadrupole Coupling in Associated Liquids

The presence of neighboring molecules influences the electric field gradient at a nuclear site, by directly providing additional charge distributions outside of the molecule and also by distorting the electronic distribution of the molecule of interest. An extreme case is a liquid in which hydrogen bonding or complex formation is present. One approach to the calculation is to consider the liquid as having a distribution of clusters of all sizes, monomers, dimers, \(n\)-mers where \(n\) is truncated at some value when the contribution to the average value is sufficiently small. Molecular geometries of each \(n\)-mer are optimized and the electric field gradients are calculated at each nuclear site in the \(n\)-mer. Molecular partition functions are calculated for each \(n\)-mer, and from thermodynamic calculations the distributions of the \(n\)-mers are obtained. The average electric field gradient for each cluster is weighted with the cluster distribution to obtain the electric field gradient values in the liquid phase. The \(^{14}\text{N}\), \(^{17}\text{O}\), and \(^{2}\text{H}\) of the carbonyl and \(\text{cis}\) and \(\text{trans}\) amides have been calculated in liquid formamide by this method, for comparison with the experimental values of NMR quadrupolar relaxation time as a function of temperature.\(^\text{100}\) Cyclic hexamers are found to be the dominant species at room temperature, consistent with structural data from neutron diffraction, low-frequency Raman, and far-infrared spectra. This method of calculation has been applied to liquid HCN, in which the calculated values for the isolated monomer, dimer, and trimer successfully predict the values known independently from pulsed Fourier transform microwave experiments on the van der Waals complexes.\(^\text{101}\) Theoretical calculations such as these, combined with measurements of the nuclear quadrupole coupling constants as a function of temperature, can provide a useful general probe of electronic changes accompanying hydrogen bonding, cluster formation, solvation, phase condensation, and other phenomena in condensed media.

### 5.4 Relation Between Chemical Shift and Electric Field Gradient Tensors

NMR measurements in single crystals permit the independent determination of the principal axis systems of the electric field gradient tensor and the shielding tensor.\(^\text{102}\) Even in the powder it may be possible to find the relative orientation of these two axis systems by referring to the known axis system for the dipolar coupling. The two axis systems are not necessarily coincident. Theoretical calculations of both the electric field gradient and the shielding tensors at the same nuclear site provide descriptions of the electronic distribution and chemical bonding which can be checked directly against experiment. They provide respectively, a measure of the bond direction and the strength of the hydrogen bond for the deuteron nucleus, for example. In materials that exhibit a distribution of nuclear sites, such as glasses or polymers, multidimensional solid-state NMR techniques permit the determination of the anisotropic chemical shift as a function of the isotropic chemical shift or of the electric field gradient as a function of the isotropic chemical shift. From such measurements, the anisotropic chemical shift of \(^{29}\text{Si}\) and the electric field gradient of \(^{17}\text{O}\) nuclei, for example, can both be used to characterize a silicate glass or other complex materials, providing complementary information.\(^\text{103,104}\) Thus, these two tensors provide local electronic information even in complex materials. With the assistance of theoretical calculations such multidimensional solid-state NMR experiments can provide answers to questions about the microscopic structure of solids, on the extent of order/disorder in cation environments, random distributions or amorphous/crystalline domains, short-range and long-range order, and so on.

### 6 INFLUENCE OF INTRAMOLECULAR GEOMETRY AND ENVIRONMENT ON NUCLEAR MAGNETIC RESONANCE PARAMETERS

The temperature dependence, mass dependence (isotope effects), and site sensitivity (dependence on secondary/tertiary structure of proteins, for example) of
chemical shifts, spin–spin couplings, and electric field gradients provide additional information about structure, dynamics, and environment of a molecule or a particular part of a molecule.

6.1 Nuclear Magnetic Resonance Parameter Dependence on Local Geometry: Bond Lengths, Bond Angles, Torsion Angles

The insight into structure and environment provided by the NMR chemical shift is obtained by a combination of theoretical calculations and experiments.\(^{(105)}\) The NMR chemical shift discriminates between the various alanine residues in the same protein molecule, between two nuclear sites identical in every way except that one has \(^{18}\)O in a neighboring bond rather than \(^{16}\)O (isotope shift studies), between a \(^{15}\)N (and \(^{13}\)C) in a dynamically averaged rather than rigid headgroup at an oriented membrane interface, for example. In most cases, theoretical calculations using innovative model fragment systems are required to interpret the relation between the structure and the chemical shift. The discrimination is afforded by the extreme sensitivity of the shielding tensor to the local geometry: the bond lengths, bond angles, and torsion angles. The mathematical surface describing the shielding tensor as a function of these geometrical parameters is called a shielding surface. Vibrational averaging over the shielding surface, weighted by the probabilities of finding the molecule at the geometries described by these parameters (the vibrational wavefunction provides these probabilities) gives average shielding values that are different for different isotopomers, gives average shielding values that are different for particular \((\phi, \psi)\) angles that characterize particular alanine residues in a protein. Thus, isotope effects on chemical shifts can be predicted; the distinguishing chemical shifts of different alanine residues in a protein can be associated with specific local conformations, leading to structure determination.

The application of quantum mechanical calculations of shielding surfaces to the structural characterization of proteins was introduced by de Dios, Pearson, and Oldfield.\(^{(106)}\) This approach has led to the possibility of secondary and tertiary protein structure determination from NMR chemical shifts in solution using \(^{13}\)C alone.\(^{(107)}\) The method is extremely powerful when combined with complementary information obtained from geometry sensitivity of other NMR parameters such as spin–spin coupling and \(^1\)H chemical shifts.\(^{(108)}\) The use of theoretical calculations of NMR shielding surfaces to elucidate structure and dynamics finds application in the gas phase, in catalysis, as well as in biomolecular systems.\(^{(105,109,110)}\)

The dependence of the spin–spin coupling, the electric field gradient and other molecular electronic properties on bond lengths and bond angles, and the observations that are the experimental manifestation of this, are similar to that discussed above for shielding. The general theoretical basis for isotope effects and temperature dependence of these properties is the same. With the assumption of the Born–Oppenheimer separation of nuclear motion from electronic motion, the mathematical surface describing the dependence of \(J\) (or other) on the geometrical parameters (such as bond lengths) exists, just as does the potential energy surface of the molecule. Averaging on the property surface is according to the probability of finding the molecule at various geometries, which in turn is determined by the vibrational wavefunctions corresponding to the potential energy surface.\(^{(111)}\) Raynes et al. have provided very good case studies of these effects on coupling constants in polyatomic molecules, including details of the theoretical surfaces, dynamic averaging, and experimental measurements of the temperature dependence of spin–spin coupling in the various isotopomers.\(^{(112–115)}\)

6.2 Intermolecular Effects

NMR shielding is extremely sensitive to intermolecular effects. This sensitivity is manifested by the very large gas-to-liquid shifts (4.4 ppm for \(^1\)H in H\(_2\)O, 19.5 ppm for \(^{15}\)N in NH\(_3\)), 77 ppm for \(^{31}\)P in P\(_4\), 120 ppm for \(^{77}\)Se in H\(_2\)Se, around 200 ppm for \(^{129}\)Xe in xenon), by the aromatic solvent-induced proton chemical shifts, and by the very large average chemical shifts observed for Xe in various media such as zeolites and polymers.\(^{(105,106)}\) Theoretical calculations of these intermolecular effects are sometimes carried out by approximating the medium as a continuum and considering the molecule in a cavity within this medium of fixed dielectric constant. Such an option is routine in many quantum mechanical software packages. Another approach is to consider the intermolecular effects in terms of electrical polarization effects of fixed partial electrical charges centered on surrounding atoms in a crystalline system. A more complete treatment is to calculate the nuclear shielding in the molecule together with the solvent at various internuclear separations and orientations and then to average such shieldings over the appropriately weighted configurations at each temperature.\(^{(116,117)}\) The effects of hydrogen bonding on the \(^1\)H shielding tensor in ice have been reproduced by calculations using 17 H\(_2\)O molecules arranged in the experimental ice configuration, for example, emphasizing the importance of long-range effects.\(^{(118)}\) While the short range effects on shielding of \(^{13}\)C, \(^{15}\)N, \(^{17}\)O, and \(^1\)H nuclei in each amino acid residue protein (the geometry dependence and hydrogen bonding) can be calculated using a model fragment, the long-range effects of neighboring residues may be considered in the same way as intermolecular effects from solvent molecules. It
has been found that such long-range electrostatic effects have an important role to play in interpreting \(^1\)H, \(^{15}\)N, and \(^{17}\)O chemical shift inequivalencies in proteins, and neighbor anisotropy has an important role in the case of \(^3\)H. Molecular dynamics (MD) has been used to produce a large number of instantaneous configurations for which the component magnitudes and directions of the \(^{15}\)N shielding tensor can be calculated in a simple model system (three \(N\)-methylacetamide complexes) constructed from a gramicidin channel in a fully hydrated phospholipid bilayer.\(^{119}\) The MD method of sampling reveals fluctuations in the tensor properties which may be used to investigate the types of NMR spectra produced during such motional averaging for a protein observed in a fluid bilayer environment.

A clear case of intermolecular effect on chemical shifts is found in the xenon atom. The use of \(^{129}\)Xe chemical shifts in studies of various electronic environments (zeolites, polymers, clays, coals, biological systems) depends on theoretical calculations of the intermolecular effects on \(^{129}\)Xe shielding in the xenon atom. The dispersion of the Xe signal in these various media is very useful as a diagnostic tool in the analysis of structure of the medium, the distribution of Xe atoms within, and the rate of exchange (diffusion) of Xe from one cage (or channel or domain) to another, as well as from within the medium to the bulk phase. The ability to reproduce the temperature dependence of the intensities and the individual chemical shifts in the \(^{129}\)Xe NMR spectrum of the various Xe\(_1\), Xe\(_2\), Xe\(_3\), \ldots, Xe\(_8\) signals observed for xenon trapped in variety of \(A\) zeolites, (Na\(_A\), Ca\(_A\),Na\(_{12-2x}\)A, K\(_A\), Ag\(_A\)) using a combination of quantum mechanical calculations and statistical mechanical averaging,\(^{117,120–123}\) permits the interpretation of the NMR observations in various other zeolites wherein fast xenon exchange leads to one signal that contains the average over all distributions.\(^{124}\) The Xe chemical shifts are very large (several hundred ppm) and discriminate between amorphous and crystalline regions in polymers and coals; however, the theoretical prediction of the Xe NMR spectrum in these more complex materials lags behind the experiments. The same approach as used in the crystalline zeolites should work in these more complex systems, provided that an appropriate model system can be introduced and tested in each case.

Theoretical approaches for intermolecular effects on \(J\) would be the same as for chemical shifts, although the observed effects are generally smaller. Intermolecular effects on electric field gradients at a nucleus can be substantial. In van der Waals dimers and higher n-mers, the nuclear quadrupole coupling constant can be sufficiently different from that found in the monomer and can be used to deduce the structure of the clusters formed. Calculations of the electric field gradient at a nucleus in a cluster treated as a supermolecule generally have to be carried out as a function of geometry, and it is usually necessary for internal coordinates to be permitted to vary with intermolecular separation. Furthermore, consistent with the strength of intermolecular forces, cluster vibrations can be very anharmonic, so averaging will have to be done accordingly. Farrar and Weinhold have carried out averaging of the electric field gradient at the \(^{14}\)N and \(^2\)H nuclei of HCN in (HCN)\(_2\) and (HCN)\(_3\) and (HCN)\(_n\) up to \(n = 6\).\(^{101}\) The interpretation of the nuclear quadrupole couplings in liquid HCN as a function of temperature also requires that the distribution of the dominant clusters be calculated by statistical mechanics. The nonpairwise additive cooperativity effects in the hydrogen bonding that are comparable in magnitude to that of dimer formation in this system cannot be neglected in the calculation of the NMR parameters. For the same reason, the NMR parameters of liquid water or ice cannot be deduced from calculations on (H\(_2\)O)\(_2\) alone.

Many interesting materials analyzed by NMR spectroscopy are made up of covalent networks. Calculations of NMR parameters in extended networks is not yet tractable. One approach to calculations in such systems is to consider models consisting of truncated clusters. For example, \(^{29}\)Si shielding, \(^{17}\)O shielding and electric field gradients, and \(^{27}\)Al electric field gradients in silicates and aluminosilicates are of great interest in the NMR analyzes of zeolite structure. Zeolites are aluminosilicates with crystalline structure which are constructed from SiO\(_4\) tetrahedra joined together by sharing edges and vertices. Al may replace Si in the lattice, with the charge balanced by extra-framework cations. Thus, the crystal is formed by a network of Al/Si atoms connected by bridging O atoms. Some clusters that have been used in calculations of NMR parameters of zeolites include fragments of the sodalite cage terminated by H atoms replacing the truncated Al or Si atoms in the extended network, or by replacing the truncated bridging oxygen atoms by H atoms.\(^{125,126}\) Another possible approach is the use of an embedded small fragment within the much larger cluster. The small fragment which consists of the nucleus of interest and its immediate neighbors, is treated ab initio quantum mechanically at an appropriate level, the rest of the atoms in the much larger truncated cluster carved out of the network being treated at a lower level (semiempirically or by molecular mechanics). Such hybrid approaches appear promising for extended covalent networks and polymers.

7 FUTURE DEVELOPMENTS

Theoretical calculations of shielding and electric field gradient tensors for isolated molecules are well in hand,
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

except where relativistic effects are important. Relativistic calculations have yet to be carried out in a theoretically rigorous manner, rather than using a patchwork of spin-free and spin–orbit contributions. Heavy nuclei, particularly transition metal nuclei, which are important components of technologically important solid materials, cannot be treated accurately until the problem of relativistic effects is solved. The extreme sensitivity of shielding and electric field gradient tensors to intermolecular effects and local geometries (imposed by longer range order and distributions) presents a distinct advantage as well as difficulties. Applications of calculations of shielding and electric field gradients to interpretations and analyses of complex systems require construction of appropriate useful models that can be tested in simpler systems and extended to complex ones. By separating the various short-range (geometrical, hydrogen bonding) and long-range intermolecular contributions to the chemical shift, a powerful tool in analyzing structure, dynamics, and environment can be realized. The approach used in proteins can be extended to other polymers and even mixtures of polymers. Theoretical calculations of spin–spin coupling constants are more difficult, even in isolated small molecules, but are slowly becoming more tractable. These have sensitivity to local geometries but are less susceptible to intermolecular effects and long-range contributions. The use of density functional techniques offers hope that larger systems can be handled, but the difficulties with the presently available approximate exchange correlation functionals naturally limit the accuracy of the results that can be obtained. When more accurate functionals become available, this will clearly be the method of choice for very large systems.

Quadrupolar Nuclei in Solid-state Nuclear Magnetic Resonance

Dieter Freude
Universität Leipzig, Leipzig, Germany

1 INTRODUCTION

The applicability of the NMR technique continues to expand in physics, chemistry, materials science, geology, biology, and medicine for either spectroscopic studies or imaging purposes. The majority of the recent applications can be found in the field of analytical chemistry. In 1998, Current Contents (Physical, Chemical and Earth Sciences) referred to about 8500 NMR studies, including 1800 studies of solids. Solid-state NMR, for which some special techniques must be used in order to obtain highly resolved spectra, is mostly applied to $^1$H or $^{13}$C nuclei with spin $I = \frac{1}{2}$. About 100 of 130 NMR isotopes have $I > \frac{1}{2}$, and the electric quadrupole interaction strongly broadens the NMR signal in the solid-state powder spectra. However, more than 400 references to solid-state NMR studies of quadrupolar nuclei in Current Contents in 1998 demonstrate that this problem could be overcome.

The demand for the characterization of inorganic materials and some recently developed experimental techniques have led to growing interest in high-resolution solid-state NMR spectroscopy of quadrupolar nuclei in powder samples. In addition, the perturbing effect of the electric quadrupole interaction is reduced at higher magnetic fields, which are now commercially available up to 21 T also for solid-state NMR spectrometers. In addition, approaches of the solid-state NMR traditionally used in the study of spin-$\frac{1}{2}$ nuclei have been adapted for use with quadrupolar nuclei, e.g. echo methods, sample spinning about the magic angle (MAS), multiple-dimensional spectroscopy, double resonance and adiabatic transfer. Some techniques, e.g. DOR and multiple-quantum transition in combination with fast spinning (MQMAS), were developed for quadrupolar nuclei with half-integer spins.

This article describes the basic theory, the line shape for first- and second-order quadrupole broadened spectra with and without magic-angle spinning (MAS) of the powder, the most important experimental techniques for the study of quadrupolar nuclei with half-integer spins such as DOR, dynamic-angle spinning (DAS), MQMAS, echo and nutation techniques, and some recent developments in deuterium NMR. Electric field gradient and chemical shift data for the most commonly studied quadrupolar nuclei with half-integer spins, $^{27}$Al, $^{23}$Na, and $^{17}$O, and a few references to recent solid-state NMR studies of some other quadrupolar nuclei are given.

Solid-state nuclear magnetic resonance (NMR) spectroscopy is mostly applied to $^1$H or $^{13}$C nuclei with the nuclear spin $I = \frac{1}{2}$, but about 100 of 130 NMR isotopes have $I > \frac{1}{2}$, and the electric quadrupole interaction strongly broadens the NMR signal in the solid-state powder spectra. The perturbing effect of the electric quadrupole interaction is reduced at the higher magnetic fields which are available at present. In addition, approaches of the solid-state NMR traditionally used in the study of spin-$\frac{1}{2}$ nuclei have been adapted for use with quadrupolar nuclei, and some techniques, e.g. double-rotation (DOR) and multiple-quantum transition in combination with fast spinning [multiple-quantum magic-angle spinning (MQMAS)], were recently developed for quadrupolar nuclei with half-integer spins.

This article describes the basic theory, the line shape for first- and second-order quadrupole broadened spectra with and without magic-angle spinning (MAS) of the powder,
we refer to recent papers by Vosegaard et al.,(1,2) which describe the up-to-date experimental techniques, and the review by Kanert and Mehring, ‘Static Quadrupole Effects in Disordered Cubic Solids’,(3) The classical papers of Volkoff et al., ‘Nuclear Electric Quadrupole Interaction in Single Crystals’,(4,5) of Das and Saha, ‘Electric Quadrupole Interaction and Spin Echoes in Crystals’,(6) and the classical review by Cohen and Reif, ‘Quadrupole Effects in NMR Studies of Solids’,(7) should also be mentioned.

For the spin–lattice relaxation of quadrupole spins, which is not considered in the present article, we refer to Chapter 7 in Freude and Haase.(9) A survey of nuclear quadrupolar frequency data published before the end of 1982 is given by Chihara and Nakamura in Landolt-Börnstein, Vol. 20.(16) Values of the chemical shift of quadrupolar nuclei in solids can be found in books such as Multinuclear NMR edited by Mason.(17) For ²H NMR we refer to other publications.(11,13,14,18) In section 10 we present as a continuation of Freude and Haase(9) some electric field gradient and chemical shift data for the most commonly studied quadrupolar nuclei with half-integer spins:²⁷Al, ²³Na and ¹⁷O. A few references to recent solid-state NMR studies of some other quadrupolar nuclei are also given.

2 BASIC THEORY

At least three Cartesian coordinate systems were used for the description of the NMR interactions: the external magnetic field in the z-direction and the radiofrequency (RF) coil in the x-direction determine the laboratory axis system (LAB) with the coordinates (x, y, z). The interaction representation is based on the coordinates

\[ x_1 = x \cos \omega_L t, \quad y_1 = \pm y \cos \omega_L t, \quad z_1 = z. \]

This system rotates around the direction of the external magnetic field with the applied RF \( \omega = 2\pi v \). The microscopic properties of the complex under study such as the dipolar interactions, the anisotropy of the chemical shift or the electric field gradient are described in the principal axis system (PAS). The principal axes (X, Y, Z) are related to the structure of the complex, e.g. for the dipolar interaction the Z-direction is parallel to the internuclear vector.

The various interactions of the nuclear spin \( I \) can be described by the corresponding Hamiltonians. In the following we use \( I \) for the spin number and \( I \) for the spin angular momentum vector and also for the corresponding vector operator (Hamiltonian). The interaction of a nuclear spin with an external magnetic field \( B \) gives the Hamiltonian (Equation 1)

\[ \hat{I} \cdot \mathbf{B} = IZB \]

where \( Z = -\gamma h I \) includes the unity matrix \( I \), the gyromagnetic ratio \( \gamma \) of the nuclear spins and Planck’s constant, \( h = 2\pi \hbar \).

For the case of a static external magnetic field \( B_0 \) pointing in the z-direction and the application of an RF field \( B(t) = 2B_0 \cos(\omega t) \) in the x-direction, we have for the external interactions Equation (2):

\[ \omega_L I_x + 2\hbar \omega_L \cos(\omega t) I_z \]

where \( \omega_L = 2\pi \nu_L = -\gamma B_0 \) denotes the Larmor frequency and the nutation frequency \( \omega_0 \) is defined as \( \omega_0 = -\gamma B_0 \). The transformation from the laboratory frame to the rotating frame gives, by neglecting the part which oscillates with twice the RF, Equation (3):

\[ \omega_0 I_x + \omega_0 I_z + \omega_L \cos(\omega t) I_z \]

where \( \Delta \omega = \omega_L - \omega \) denotes the resonance offset.

In addition to the external interactions there exist internal interactions of a nuclear spin, which can be efficiently expressed in the notation of irreducible tensor operators.(20) The definition and the most important feature (coordinate rotation) of an irreducible tensor operator of rank \( k \) with \( (2k + 1) \) components is given by Equation (4):

\[ P_R T^{(k)} P_R^{-1} = \sum_{q=-k}^{k} T^{(k)}_{q} D^{(k)}_{q}(R) \]
with the Euler angles $\alpha$, $\beta$, and $\gamma$. The elements $d^{(k)}_{m_1m_2}(\beta)$ of the reduced Wigner matrices depend on the angles $\alpha$ and $\gamma$. They are given in Table 1 for rank 2; values for rank 4 can be found in Zheng et al.\textsuperscript{(21)} As presented in Figure 1, a positive rotation to a frame $(x', y', z')$ about the Euler angles includes the rotation $\alpha$ about the original $z$ axis, the rotation $\beta$ about the obtained $y'$ axis and the rotation $\gamma$ about the final $z''$ axis [cf. Rose\textsuperscript{(22)}].

$^a$ The following abbreviations are used: $a = \cos \frac{\beta}{2}$, $b = \sin \frac{\beta}{2}$, \quad $c = \sqrt{2}ab = \frac{1}{\sqrt{2}}\sin \beta$ and $d = a^2 - b^2 = \cos \beta$.

The commutator shows another important feature of an irreducible tensor operator (Equations 7–9)\textsuperscript{(20)}

\[
[I_\alpha, T_q^{(k)}] = qT_q^{(k)}
\]

and

\[
[I_{\pm 1}, T_q^{(k)}] = \pm \sqrt{\frac{1}{2}(k(k+1) - q(q \pm 1))}T_{q \pm 1}^{(k)}
\]

where \((kk'q'q'kk'Q)\) are Clebsch–Gordan coefficients.\textsuperscript{(20)} The scalar product of the operators $T_q^{(k)}$ and $V_q^{(k)}$ is simpler (Equation 11): 

\[
T_q^{(k)} \cdot V_q^{(k)} = \sum_{q'=-k}^{+k} (-1)^q T_q^{(k)} V_{q'}^{(k)}
\]

Fortunately, most internal interactions in the NMR can be written in this form.\textsuperscript{(23)} In the following the operators $T_q^{(k)}$ and $V_q^{(k)}$ act on two noninteracting systems, the nuclear spin coordinates and the spatial coordinates (lattice parameters), respectively.

In the strong external magnetic field it holds for the internal interactions by neglecting the nonsecular part of the corresponding Hamiltonian that (Equation 12)

\[
[T, \text{internal}] = 0
\]

Comparison of Equation (12) with Equation (7) shows that only tensor elements with $q = 0$ contribute to the secular part of the internal Hamiltonians in a strong external magnetic field, if the system is described in the laboratory frame (LAB). However, the microscopic properties of the system are described in the PAS and a rotation of the coordinates from the PAS to the LAB by means of the Wigner matrix elements $D^{|q|}_{q q}(R)$ must be performed. For example, the element $q = 0$ of the tensor $V_q^{(k)}$ is obtained by Equation (13):

\[
V_0^{(k)}(\text{LAB}) = \sum_{q'=-k}^{+k} V_q^{(k)}(\text{PAS}) D^{|q|}_{q q}(R)
\]

Operators of rank 0 are invariant with respect to rotations. For the chemical shift we have (Equations 14–16)

\[
\gamma_0 = \frac{1}{\sqrt{3}} I_0 B_0
\]

\[
\nu_0 = \sqrt{3} \sigma_{\text{iso}}
\]
and
\[ \text{isotropic chemical shift} = -\gamma \sigma_{\text{iso}} I_z B_0 \] (16)
where \( \sigma_{\text{iso}} \) is the isotropic part of the shielding tensor (Equation 17):
\[ \sigma_{\text{iso}} = \frac{\sigma_{XX} + \sigma_{YY} + \sigma_{ZZ}}{3} \] (17)

Rank 0 operators do not contribute to dipolar interactions or quadrupolar interaction in first order. The contribution of the rank 1 operators can be neglected for all considered interactions. Therefore, anisotropy of the chemical shift, dipolar interactions and quadrupolar interactions in first order can be described by rank 2 operators in the form of Equation (18):
\[ = C \sum_{q=-2}^{+2} (-1)^q T^{(2)}_q V^{(2)}_{q} \] (18)

Several contributions as described in Table 2 can be superimposed. The elements of the shielding tensor \( \sigma \) (trace 3\( \sigma_{\text{iso}} \)) and of the traceless tensor of the electric field gradient \( V \) [which must not confused with the operator \( V^{(k)} \)] are given in the PAS. Parameters of the anisotropy are \( \delta = \sigma_{ZZ} - \sigma_{\text{iso}} \) for the chemical shift and \( V_{ZZ} = eq \) for the electric field gradient, where \( e \) denotes the elementary charge and the value \( q \) alone has no physical meaning in SI units. \( Q \) is the quadrupolar moment and \( eQ \) is called the electric quadrupolar moment. The asymmetry parameter \( \eta \) is in the range \( 0 \leq \eta \leq 1 \). With the convention \( |V_{ZZ}| \geq |V_{YY}| \geq |V_{XX}| \) or \( |\sigma_{ZZ} - \sigma_{\text{iso}}| \geq |\sigma_{YY} - \sigma_{\text{iso}}| \geq |\sigma_{XX} - \sigma_{\text{iso}}| \), we obtain (Equations 19 and 20)
\[ \eta = \frac{V_{XX} - V_{YY}}{V_{ZZ}} \] (19)

or
\[ \eta = \frac{\sigma_{XX} - \sigma_{YY}}{\sigma_{ZZ} - \sigma_{\text{iso}}} \] (20)

Equation (21):
\[ I_{\pm 1} = \mp \frac{1}{\sqrt{2}} (I_x \pm i I_y) \] (21)

and Equation (22):
\[ F(\alpha, \beta, \eta) = \left( \frac{3 \cos^2 \beta - 1}{2} + \frac{\eta}{2} \sin^2 \beta \cos 2\alpha \right) \] (22)

are used in Table 2. The last row in Table 2 gives components which were transformed from the PAS into the LAB by the Euler angles \( \alpha \) and \( \beta \) using Equation (13) for rank 2. With Equation (18) we obtain for the secular part of the Hamiltonian in the LAB for quadrupolar interaction in the first order (Equation 23)
\[ q = \frac{eQ V_{ZZ}}{4I(2I-1)} [3I_z^2 - I(I+1)] \times (3 \cos^2 \beta - 1) + \frac{\eta}{2} \sin^2 \beta \cos 2\alpha \] (23)

The quadrupolar coupling constant \( C_{\text{qcc}} \) is commonly defined according to Equation (24):
\[ C_{\text{qcc}} = \frac{e^2 qQ}{h} \] (24)

* The dipolar interaction is the homonuclear one. For heteronuclear dipolar interactions \( T^{(2)}_0 \) must be substituted by \( \sqrt{\frac{3}{2}} I_{\pm 0} I_{\pm 3} \).
QUADRUPOLAR NUCLEI IN SOLID-STATE NUCLEAR MAGNETIC RESONANCE

However, for the quadrupolar frequency, \(v_Q\) or \(w_Q\), different definitions exist in the literature. We use the values according to Equation (25):

\[
v_Q = \frac{3e^2 qQ}{2I(2I-1)\hbar} = \frac{3C_{qee}}{2I(2I-1)}
\]  

or Equation (26):

\[
w_Q = \frac{3e^2 qQ}{2I(2I-1)\hbar}
\]  

which were introduced for half-integer spin nuclei in the field of nuclear quadrupolar resonance (NQR) by Das and Hahn,\(^{24}\) and established by Abragam\(^{19}\) also for NMR. For different definitions in the case of half-integer spin nuclei, see Freude and Haase\(^{9}\) (p. 33) and some papers following Frydman and Harwood.\(^{25}\) For integer spins even less notational consistency exists, cf. Hoatson and Vold\(^{11}\) (pp. 5 and 8). Equation (24) is still valid, but the definition of the quadrupolar frequency after Equation (26) is seldom used for spin-1 nuclei.

By substituting \(V_{zz} = eq\) and using the angular dependent quadrupole frequency (Equation 27)

\[
v'_Q = v_Q \left( \frac{3\cos^2 \beta - 1}{2} + \frac{\eta}{2} \sin^2 \beta \cos 2\alpha \right)
\]  

one can write (Equation 28)

\[
\frac{v'_Q}{v_Q} = \frac{h}{6}[3I_z^2 - I(I + 1)]
\]  

Equation (28) represents the first-order contribution of the quadrupolar interaction in the strong external magnetic field. From the second-order contribution the secular part with respect to \(I_z\) is given by Equation (29):

\[
\frac{v''_Q}{v_Q} = \frac{h^2}{9\nu L} \left\{ 2I_z^2 - I(I + 1) + \frac{1}{4} V_{-1}V_1 
+ I_z I_{-2} - I(I + 1) + \frac{1}{2} V_{-2}V_2 \right\}
\]  

The components \(V_{p,p'}\) in Equation (29) correspond to the LAB. They can be obtained from the components in the PAS by means of Equation (13).

The homonuclear dipolar interaction of a pair \((i, k)\) of spins with the distance \(r_{ik}\) and an angle \(\theta\) between the internuclear vector and the direction of the external magnetic field is described by the Hamiltonian (Equation 30)

\[
D = \frac{\hbar_0}{4\pi \gamma_i \gamma_k r_{ik}^2} \left( \frac{3\cos^2 \theta_{ik} - 1}{2r_{ik}^2} \right) (3I_z, I_{\pm k}, -I, I_k)
\]  

and it holds that \(\gamma_i = \gamma_k\). For heteronuclear dipolar interactions we have \(\gamma_i \neq \gamma_k\) and \((3I_z, I_{\pm k}, -I, I_k)\) in Equation (30) must be substituted by \((I_z, I_{\pm k})\).

The Hamiltonian of the chemical shift is the sum of the isotropic and the anisotropic contributions (Equation 31):

\[
CS = \gamma_0 B_0 I_z \sigma_{iso} + \delta \left( \frac{3\cos^2 \beta - 1}{2} + \frac{\eta}{2} \sin^2 \beta \cos 2\alpha \right)
\]  

3 EXCITATION

The energy of a spin interaction can be described by the size of the corresponding Hamiltonian \(\|\|\). For NMR the usual sequence is \(\| 0 \| \gg \| r \| \gg \| 0 \|, \| d \|, \| CSA \|.\) Expressed in frequencies: the Larmor frequency (\(\| 0 \|\)), cf. Equation (2), is of the order of magnitude of 10–1000 MHz, the nutation frequency (\(\| r \|\)), cf. Equation (2), is of the order of magnitude of 1–400 kHz and the internal interactions are smaller than the RF field strength. However, the latter is sometimes not correct for quadrupolar nuclei in solids. We can assume the relation \(\| 0 \| \gg \| r \| \gg \| d \|, \| CSA \|\) and have to distinguish the well-defined cases \(\| r \| \gg \| d \|\) or \(\| r \| \ll \| d \|\) and the ill-defined intermediate case (**+**). A so-called hard pulse can perform a nonelective excitation of the whole quadrupolar broadened spectrum, if the RF field strength meets (**). The soft pulse (**+) excitation is limited to any single transition \((m = -I, -I + 1, \ldots, I - 1)\) in a single crystal or to the central transition \((m = -\frac{1}{2})\) for powdered materials. Here the transition \(m\) denotes the transition between the magnetic quantum numbers \(m \longleftrightarrow m + 1\).

The excitation of quadrupolar nuclei with half-integer spins is discussed in detail by Freude and Haase.\(^{10}\) For a short description of the problem of excitation of any NMR transition, we start from the basic equation for the frequency spectrum of a rectangular pulse with the duration \(\tau\) and the carrier frequency \(v_0\) with \(\delta v = v - v_0\) (Equation 32):

\[
f(\delta v) = \frac{1}{\tau} \cos(2\pi \delta v \tau) \, dr = \frac{\sin(\pi \delta v \tau)}{\pi \delta v \tau}
\]  

It has its maximum \(f(\delta v) = 1\) for \(v = v_0\) and the first nodes in the frequency spectrum occur at \(\delta v = \pm 1/\tau\). The spectral energy density \(E\) is proportional to the square of the RF field strength which includes the offset dependence of Equation (32). If we define the usable bandwidth of excitation \(\delta v_{1/2}\) in analogy to electronics by Equation (33):

\[
E(v = \pm \delta v_{1/2}) = \frac{1}{2} E(v = v_0)
\]  

or Equation (34):

\[
f^2(v = \pm \delta v_{1/2}) = \frac{1}{2} f^2(v = v_0)
\]
If the single pulse is substituted by a composite pulse, a designed broadband or narrowband excitation can be achieved.\(^{28}\)

The intensity of the FID \(G(t = 0)\) after the pulse with the RF field strength \(w_{\text{RF}}\) and the duration \(\tau\) is, for nonselective excitation of all transitions \(m \leftrightarrow m + 1\), given by Equation (37):\(^{29}\)

\[
G_{m,m+1}^{\text{nonselective}}(0) = \frac{3[I(I+1)-m(m+1)]}{2I(I+1)(2I+1)} \sin w_{\text{RF}}\tau \quad (37)
\]

Equation (37) gives also the relative intensities of all transitions, e.g. 12/30, 9/35 and 4/21 for the central lines in the case of nonselective excitation of the \(I = \frac{3}{2}, \frac{5}{2}\) and \(\frac{7}{2}\) nuclei, respectively. The selective excitation of a single transition can be described by Equation (38):\(^{29}\)

\[
G_{m,m+1}^{\text{selective}}(0) = \frac{3\sqrt{I(I+1)-m(m+1)}}{2I(I+1)(2I+1)} \sin \sqrt{I(I+1)-m(m+1)}w_{\text{RF}}\tau \quad (38)
\]

Comparison with Equation (37) reveals that the maximum observed intensity is reduced by \(\sqrt{I(I+1)-m(m+1)}\), but the effective nutation frequency is enhanced by the same value. For the central transition, \(m = -\frac{1}{2}\), we obtain Equation (39):

\[
v_{\text{eff}}^m = (I + \frac{1}{2})w_{\text{RF}} \quad (39)
\]

Thus, for the selective excitation of the central transition, the optimum pulse duration is equal to the duration of a nonselective \(\pi/2\) pulse divided by \(I + \frac{1}{2}\). The RF power should be as low as possible. Second-order quadrupolar broadening, the chemical shift anisotropy and dipole broadening give the lower limit for the RF power which should be applied, in order to excite the full central transition in powder spectra. Then, only a small portion of the satellite powder spectra is also excited. The partly selective excitation of more than one transition can be treated only numerically.\(^{29}\)

The problem of ill-defined excitation in cases of strong quadrupolar interaction can be overcome by adiabatic frequency sweeps. Adiabatic passages are well known in NMR.\(^{29}\) Kentgens\(^{27}\) established in 1991 the quantitative excitation of a half-integer spin system by a frequency-stepped adiabatic half-passage (FSAHP) on the basis of an approach of Sindorf and Bartuska\(^{28}\) and introduced in 1999 double-frequency sweeps (DFS) in static, MAS and MQMAS NMR experiments on the basis of an appropriate time-dependent amplitude modulation to the carrier frequency, which was applied before by Fu et al.\(^{29}\) to integer spin systems in single crystals.

In the FSAHP, the spin system is far off-resonance at the beginning of the irradiation. The frequency is then
stepped through the region of resonances slowly enough that the density operator can follow the Hamiltonian. Switching off the RF power at the resonance position of the central transition creates a single-quantum coherence like a $\pi/2$ pulse applied to a spin-1/2 system. A full passage would be comparable to a nonselective $\pi$ pulse. A frequency sweep that adiabatically inverts the satellite transitions, in order to transfer magnetization to the central levels and increase the intensity of the corresponding signal, was introduced by Haase and Conradi.\(^{(30)}\) The combination of this population enhancement with cross-polarization (CP) from \(^{27}\)Al to \(^{17}\)O was demonstrated.\(^{(31)}\) A DFS can be generated by an amplitude modulation of the RF which causes two sidebands that are swept from a start frequency to a final frequency during the pulsing.\(^{(32)}\) The authors claim that the DFS technique enhances the signal intensity also in MQMAS experiments.

The exclusive detection of the $\pm 1/2 \leftrightarrow \pm 3/2$ transitions, which is based on a central-transition signal enhancement by means of an adiabatic RF sweep was introduced by McDowell et al.\(^{(33)}\) in order to simplify the spectra and increase the sensitivity. Another approach to resolution enhancement by population transfer between Zeeman levels of the quadrupolar spin system with selective pulses and adiabatic frequency sweeps was first applied to $^{63}\text{Cu}$ in superconductors by Haase et al.\(^{(34)}\)

Another NMR technique that uses adiabatic passage in combination with rotational echo and double resonance was introduced by Gullion.\(^{(35)}\) He combined the principles of rotational-echo double resonance (REDOR),\(^{(36)}\) with the transfer-of-populations double-resonance (TRAPDOR) developed by Grey et al.\(^{(37)}\) The so-called REAPDOR NMR technique allows first, like TRAPDOR, the indirect detection of signals which are too broad to be directly observable for the single-resonance observation of the quadrupolar nucleus and second, like REDOR, the measurement of distances between spin pairs.\(^{(38)}\)

CP excites a spin system by polarization transfer from another spin system. CP was introduced by Hartmann and Hahn\(^{(39)}\) and is described in detail in the textbook by Slichter.\(^{(40)}\) S. Vega\(^{(41)}\) first applied static CP to half-integer nuclei and A.J. Vega\(^{(42)}\) considered the spin dynamics of cross-polarization magic-angle spinning (CPMAS) NMR as a function of the ratio $v_{FW}^{\text{CP}}/v_{FW}^{\text{rot}}$. Applications until 1992 are reviewed in Chapter 6.2 of Freude and Haase.\(^{(9)}\) Recent discussions about the spin-locking efficiency of the CPMAS NMR of half-integer quadrupolar nuclei were presented by Hayashi\(^{(43,44)}\) and Sun et al.\(^{(47)}\) The combination of CP with other NMR techniques will be considered in sections 5–7.

### 4 LINE SHAPE OF STATIC AND MAGIC-ANGLE SPINNING NUCLEAR MAGNETIC RESONANCE SPECTRA

The following considerations concern the angular dependent quadrupolar shift. Assuming the resonance offset to be zero, the quadrupolar shift should be given as $v - v_L$. For simplicity, we omit $-v_L$, the subtraction of the Larmor frequency. The conventions $v_{m,m+1}$ and $v_{m,-m}$ for single-quantum transitions and symmetric transitions, respectively, are used here in agreement with the majority of the literature. For the central transition $v_{-1/2,+1/2}$ we have $m = -1/2$. Then, the first-order quadrupolar shift becomes, with $v_{Q}$ from Equation (27), Equation (40):

$$v_{m,m+1} = v_{Q}(m + \frac{1}{2})$$  \hspace{1cm} (40)

for single-quantum transitions, which means zero for the central transition $m = -1/2$. The first-order quadrupolar contribution is zero for all symmetric transitions $m \leftrightarrow -m$. See Equation (28) and note that $I_z = m$ is a number in this case.

The second-order quadrupolar shift can be obtained by means of Equation (29) as Equation (41):

$$v_{m,m+1} = \frac{-v_{Q}^{2}}{18v_{L}} \{[24m(m+1) - 4I(I+1) + 9]V_{1}V_{-1}$$

$$+ [6m(m+1) - 2I(I+1) + 3]V_{2}V_{-2}\} \hspace{1cm} (41)$$

or Equation (42):

$$v_{m,-m} = \frac{-m v_{Q}^{2}}{18v_{L}} \{[4I(I+1) - 8m^2 - 1]V_{1}V_{-1}$$

$$+ [2I(I+1) - 2m^2 - 1]V_{2}V_{-2}\} \hspace{1cm} (42)$$

for single or symmetric quantum transitions, respectively. The components $V_{j}$ are given in the LAB and can be described, with the Wigner matrices of rank 2, as functions of corresponding values in the PAS, which are given in Table 2. The $V_{j}/V_{-j}$ terms in Equations (41) and (42), therefore, can be written also as Wigner matrices for which the rank goes up to 4. Amoureux\(^{(48)}\) gave a corresponding equation with the coefficients for the transformation of Equation (42) from the LAB into the PAS.

The second-order quadrupolar shift of the central transition can also be obtained with $m = -1/2$ from Equations (41) and (42) (Equation 43):

$$v_{-1/2,+1/2} = \frac{-v_{Q}^{2}}{6v_{L}} \frac{3}{4} I(I+1) - \frac{3}{4}$$

$$\times (A \cos^2 \beta + B \cos^2 \beta + C) \hspace{1cm} (43)$$
The components $V_p V_{-p}$ are substituted now by functions depending on the Euler angles $\alpha$ and $\beta$ and the asymmetry parameter $\eta$. The functions $A$, $B$, $C$ (Table 3, static) were first used by Narita et al.\textsuperscript{49} in order to calculate the second-order powder pattern of the central transition for a static (nonrotating) sample. Müller\textsuperscript{50} showed that in the case of very fast MAS of the samples Equation (43) holds with other functions $A$, $B$, $C$ (Table 3, MAS).

In order to deduce quadrupole parameters from experimentally obtained spectra, it is usual to fit the experimental spectrum with calculated spectra using a utility program of the spectrometer software. Figures 2 and 3 show spectra, which were obtained with the program WINFIT from Bruker. If the spinning speed is not large compared with the second-order shift, the average Hamiltonian can be used for numerical calculations.

Equation (43) allows an analytical determination of the center of gravity $v_{cg}$ for the powder pattern, which is called the isotropic quadrupolar shift of the signal of the central transition. This shift is not influenced by a rotation of the sample. We denote it as $v_{iso} Q$ (Equation 44):

$$v_{iso} Q = -\frac{v_0^2}{30\nu L} I(I + 1) - \frac{3}{4} \left(1 + \frac{\eta^2}{3}\right)$$  \hspace{1cm} (44)

An important parameter of the powder line shape $f(v)$ is the second moment defined by Equation (45):

$$M_2 = \frac{\int (v - v_{iso})^2 f(v) dv}{\int f(v) dv}$$  \hspace{1cm} (45)

with $\int f(v) dv = 1$. The dimension Hz$^2$ of $M_2$ changes to s$^{-2}$ or T$^2$ if the line shape is given as $f(w)$ or $f(B)$, respectively. The square root of $M_2$ characterizes the second-order broadening of the signal. Equations (46–48) give the second moments as a function of $v_{iso}$ for the static and for the MAS spectrum and in addition the narrowing factor, which can be achieved by the application of MAS to the second-order quadrupolar broadening of the central transition:

$$M_2^{\text{static}} = v_{iso}^2 \frac{23}{7}$$  \hspace{1cm} (46)

$$M_2^{\text{MAS}} = v_{iso}^2 \frac{1}{4}$$  \hspace{1cm} (47)

$$\frac{M_2^{\text{static}}}{M_2^{\text{MAS}}} = \sqrt{\frac{92}{7}} \approx 3.6$$  \hspace{1cm} (48)

Equations (46–48) in combination with Equation (44) allow the determination of $v_{iso} \sqrt{1 + \eta^2}/3$ from the second moment of the line shape, if the latter is exclusively broadened by second-order quadrupolar interaction. However, other contributions to the second moment of the static line shape should also be considered. The
anisotropy of the chemical shift gives Equation (49):

$$M_{2}^{\text{sa}} = \frac{4}{9} \left( \Delta \sigma_{\nu_{1}} \right)^{2} \left( 1 + \frac{\eta^{2}}{3} \right)$$  \hspace{1cm} (49)$$

where $\Delta \sigma = \sigma_{ZZ} - (\sigma_{XX} - \sigma_{YY})/2$ denotes the total anisotropy and $\eta$ is the asymmetry parameter (cf. Equations 20 and 21) and $\nu_{\text{iso}}$ in Equation (45) must be taken as the isotropic value of the chemical shift.

If the dipolar interaction is small compared with the quadrupolar interaction, the spin flipping between different transitions is prohibited, and the second moment due to the dipolar interaction is modified.\(^9,10\) We will give here only the equations for dominating dipolar interaction. The dipolar second moment of a spin system consisting of $N$ resonant spins of type 1 (homonuclear interaction) and $M$ nonresonant spins of type $S$ (heteronuclear interaction) can be determined by the dimensionless Equation (50):

$$M_{2}/Hz^{2} (\gamma_{1}/2\pi)^{2} = \frac{M_{2}/s^{-2}}{\gamma_{1}^{2}} = M_{2}/T^{2} = \frac{C_{1}}{r_{1}^{2}/m^{6}} + \frac{C_{S}}{r_{S}^{2}/m^{6}}$$  \hspace{1cm} (50)

with (Equations 51–54)

$$C_{1} = \frac{3}{5}I(1 + 1) \frac{\mu_{0}}{4\pi} \frac{2}{I^{2}} \gamma_{1}^{2}h^{2}$$  \hspace{1cm} (51)

$$C_{S} = \frac{4}{15}S(S + 1) \frac{\mu_{0}}{4\pi} \frac{2}{I^{2}} \gamma_{S}^{2}h^{2}$$  \hspace{1cm} (52)

$$\frac{1}{r_{1}^{2}} = \frac{1}{N} \sum_{i=1}^{N} \sum_{k=1}^{N} \frac{1}{r_{1k}^{2}}$$  \hspace{1cm} (53)

$$\frac{1}{r_{S}^{2}} = \frac{1}{N} \sum_{i=1}^{N} \sum_{k=1}^{M} \frac{1}{r_{1k}^{2}}$$  \hspace{1cm} (54)

The value $C_{S}$ of a nonresonant nucleus can be easily calculated from the value of the same resonant nucleus $C_{1}$ by $C_{S} = C_{1} \times 4/9$. If in Equation (50) the unit of the magnetic flux density $T$ is substituted by $10$ Hz (this corresponds to the old cgs unit gauss) and the unit $m$ is substituted by the old unit $\AA$, then the values $C_{1}$ can be taken from Table 4.

Another dimensionless equation is very helpful in order to correlate the second moment of a line, which is broadened by any interaction, to the line width, which is commonly described by the full width at half-maximum (fwhm $\equiv \delta \nu_{1/2}$). Under the assumption of a gaussian line shape we obtain, for $M_{2}/s^{-2} = \gamma_{1}^{2}M_{2}/T^{2} = (\gamma_{1}/2\pi)^{2}M_{2}/Hz^{2}$, cf. Equation (50), with $T_{2}$ as the transversal relaxation time and the line width $\delta \nu$ given in hertz. Equation (55):

$$M_{2}/s^{-2} = \frac{2}{(T_{2}/s)^{2}} = (\delta \nu_{1/2}/Hz)^{2} \frac{\pi^{2}}{ln 4} \approx 7.12(\delta \nu_{1/2}/Hz)^{2}$$  \hspace{1cm} (55)

Now we go back to Equation (41) and consider the MAS spectra of the satellite transitions in addition to the central transition. Samoson\(^51\) has shown that the second-order quadrupolar shift of the $m \leftrightarrow m + 1$ transition can be split into an isotropic part describing the center of gravity of the quadrupolar shift and an angular-dependent part (Equation 56):

$$v_{m,m+1} = -\frac{V_{Q}^{2}}{20\nu_{L}} \left( I(1 + 1) - 9m(m + 1) - 3 \right) \frac{1 + \eta^{2}}{3}$$

$$- \left( \frac{V_{Q}^{2}}{20\nu_{L}} I(1 + 1) - \frac{17}{3}m(m + 1) - \frac{13}{6} \right) \times \left( A \cos^{4} \beta + B \cos^{2} \beta + C \right)$$  \hspace{1cm} (56)

with (Equations 57–59)

$$A = \frac{105}{16} - \frac{8}{35} \eta \cos 2\alpha + \frac{35}{48} \eta^{2} \cos^{2} 2\alpha$$  \hspace{1cm} (57)

$$B = -\frac{45}{8} + \frac{5}{12} \eta^{2} + 5\eta \cos 2\alpha - \frac{35}{24} \eta^{2} \cos^{2} 2\alpha$$  \hspace{1cm} (58)

$$C = +\frac{9}{4} + \frac{1}{8} \eta^{2} - \frac{5}{8} \eta \cos 2\alpha + \frac{35}{48} \eta^{2} \cos^{2} 2\alpha$$  \hspace{1cm} (59)

For the central transition, $m = -\frac{1}{2}$, Equation (56) corresponds to Equation (43) and the isotropic, upper part in Equation (56) corresponds to Equation (44). The true value of the isotropic chemical shift can be determined from the experimentally obtained isotropic shift (center of gravity of the signal), if the isotropic quadrupolar shift can be determined as shown below.\(^10,51,52\) For nonselective excitation, or at least partially selective excitation, MAS sidebands can be observed which are just outside of the spectral range of the static spectrum of the central transition. Their main intensity results from the $\pm \frac{1}{2} \leftrightarrow \pm \frac{1}{2}$ transitions, whereas the center band

results mainly from the $+\frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition. The average resonance position of two equal-order sidebands can be obtained experimentally as the center of gravity of the corresponding sidebands. Thus, the difference $\Delta = v_{\text{iso}} Q_{+1/2,1/2} - v_{\text{iso}} Q_{-1/2,1/2}$ of the average resonance position of two first satellite sidebands to the center of gravity of the central band (central transition) can be measured and compared with the corresponding difference derived from Equation (56) (Equation 60):

$$\Delta = -\frac{v_{\text{iso}}^2}{30 v_L} \left( 1 + \frac{\eta^2}{9} \right) \frac{9}{3} (1 + \eta^2)^2 \frac{1}{3}$$

Finally, the combination of Equations (56) and (60) gives the isotropic quadrupolar shift of the central band, which for $I = \frac{3}{2}$ is equal to $v_{\text{iso}} Q_{+1/2,1/2} = \Delta 8/9$.

This procedure for the determination of the quadrupolar shift or other quadrupolar parameters was introduced by Samoson.$^{(51)}$ It is convenient for $I = \frac{3}{2}$ nuclei, because the linewidth of their $\pm \frac{1}{2} \leftrightarrow \pm \frac{1}{2}$ satellites is decreased by a factor of 0.3 with respect to the central line. Jäger used this sideband analysis for the study of various inorganic compounds$^{(10)}$ and denoted it SATRAS (satellite-transition spectroscopy).

Now we go back to Equation (42) and use the representation of Amoureux$^{(48)}$ for the shift of a symmetric transition in the case of very fast sample rotation around the magic angle $\theta = \arccos \sqrt{3}^{-1/2} \approx 54.74^\circ$. Then, the contributions from the rank 2 components disappear and we obtain$^{(53)}$ Equation (61):

$$v_{p/2,-p/2} = v_{\text{iso}} Q(p) + v_{\text{aniso}} Q(p)$$

$$= \frac{pv_{\text{iso}}^2}{90 v_L} \left( 3 + \frac{\eta^2}{4} \right) \left( I(I+1) - \frac{3}{4} \right)^2$$

$$- \frac{pv_{\text{iso}}^2}{12960 v_L} \left( 18 + \frac{\eta^2}{4} \right) d_{4,0}^{(0)}$$

$$+ \sqrt{360} \eta d_{2,0}^{(0)} \cos 2\alpha + \sqrt{70} \eta^2 d_{4,0}^{(0)} \cos 4\alpha$$

$$\times \left\{ 36(I+1) - 17p^2 - 10 \right\} \left( -\frac{9}{28} \right)$$

$$\times (35 \cos^4 \theta - 30 \cos^2 \theta + 3)$$

where $p$ denotes the quantum level $pQ$ and symmetric coherences with the notation $p/2 \leftrightarrow -p/2$ instead of $m \leftrightarrow -m$ are considered. The Euler angles ($\alpha, \beta$) describe the spinner axis with respect to the PAS. The elements $d_i$ of the reduced Wigner matrices are related to $\beta$ by Equations (62–64):

$$d_{4,0}^{(4)} = \frac{1}{8} (35 \cos^4 \beta - 30 \cos^2 \beta + 3)$$

$$d_{2,0}^{(4)} = \frac{\sqrt{10}}{8} (7 \cos^2 \beta - 1) \sin^2 \beta$$

Equation (61) still contains a function of the rotor angle $\theta$ in the last brackets, in order to give one basic equation for MQMAS and DOR as well: if we insert the magic angle $\theta = \arccos \sqrt{3}^{-1/2} \approx 54.74^\circ$, then the value of the last brackets is equal to one and Equation (61) can be used as the basic equation for MQMAS NMR (cf. section 6). If we consider a DOR and the second rotor angle is fixed to $\arccos (6 \pm \sqrt{96}/5) / 14 \approx 30.56^\circ$ or $70.12^\circ$, then the value of the last brackets in Equation (61) is equal to zero and the total anisotropic part of Equation (61) disappears. For the central transition, $p = -1$, only the isotropic quadrupolar shift remains, which can be directly observed by DOR NMR. The isotropic contribution in Equation (61) is identical with Equation (44) and with the isotropic part of Equation (56), if the central transition is considered ($p = -1$ and $m = -\frac{1}{2}$).

### 5 DOUBLE-ROTATION AND DYNAMIC-ANGLE SPINNING

Samoson et al.$^{(54)}$ succeeded in 1988 in building a double-rotor probe. The outer rotor, inclined by $\beta_2 = 54.74^\circ$ with respect to the external field, rotated at about 400 Hz, and had a diameter of 20 mm. The sample in the inner rotor, 5 mm diameter, rotated at about 2 kHz, and the angle between both axes of rotation was $\beta_1 = 30.56^\circ$.$^{(54)}$

A torque-free rotation can be achieved only for a certain ratio of $k = w_1 / w_2$. The two contributions to the inner-rotor angular velocity are $w_1$ and the angular velocity $w_2$ imposed by the outer rotor. The latter can be decomposed into one component $w_2 \cos \beta_1$ along the $z$-axis of the inner rotor and another component $w_2 \sin \beta_1$ perpendicular to this axis in $y$-direction, so that $y$-direction, axis $z$ of the inner rotor, and axis $Z$ of the outer rotor are in one plane. Thus, $w_1 = 0$, $w_y = w_2 \sin \beta_1$, $w_z = w_1 + w_2 \cos \beta_1$, and the resulting angular momentum $L$ must be in the $Z$-direction in order to be torque-free$^{(55)}$ (cf. Figure 4) (Equation 65):

$$\tan \beta_1 = \frac{J_y w_2 \sin \beta_1}{J_z (w_1 + w_2 \cos \beta_1)}$$

For $\beta_1 = \arccos (6 \pm \sqrt{96}/5) / 14 \approx 30.56^\circ$, we obtain Equation (66):

$$\frac{w_1}{w_2} \equiv \frac{v_{\text{inner}}}{v_{\text{outer}}} = k = \frac{6 + \sqrt{96}/5}{14} \left( \frac{J_z}{J_z} - 1 \right)$$

$$\approx 0.86 \left( \frac{J_z}{J_z} - 1 \right)$$

...
and the usual design of the inner rotor gives values of $J_z/J_x$ so that $5 < k < 6$. Wu et al.\textsuperscript{(55)} explained that the spinning system is in a stable state when the torque-free condition, which is given by Equation (66), is slightly violated and the frequencies obey Equation (67):

$$v_{\text{inner}} = k v_{\text{outer}} + \Delta v_{\text{inner}}$$

where the excess of the inner frequency $\Delta v_{\text{inner}}$ is about 1 kHz.

The application of rotation-synchronized pulses has been shown to be effective in eliminating half of the DOR sidebands.\textsuperscript{(56)} The total suppression of sidebands can be achieved by the application of additional pulses\textsuperscript{(57)} and by application of the magic-angle turning technique.\textsuperscript{(58)} A theoretical consideration of the DOR sidebands can be found in the literature.\textsuperscript{(59–61)}

DOR NMR gives accurate values of the isotropic shift, $\delta_{\text{iso}}$, of the NMR of a quadrupolar nucleus. Two shift effects are superimposed: the isotropic quadrupolar shift, which is described in Equation (44), and the isotropic value of the chemical shift, which was introduced in Equation (16). We substitute $\delta_{\text{iso}}$, the isotropic part of the shielding tensor, by the value of the chemical shift $\delta_{\text{CS iso}} = \sigma_{\text{ref}} - \sigma_{\text{iso}}$ (with respect to a given isotropic chemical shift of a reference compound). Then we substitute the second-order quadrupolar shift $\delta_{\text{Q iso}}$ in Equation (44) by the dimensionless value $\delta_{\text{Q iso}} = (v_{\text{Q iso}}/v_L)$. In this notation we obtain for the observed isotropic shift in the DOR experiment Equation (68):

$$\delta_{\text{DOR}} = \delta_{\text{CS iso}} + \delta_{\text{Q iso}}$$

$$= \delta_{\text{CS iso}} - \frac{v_Q^2}{30v_L^2} I(I+1) - \frac{3}{4} \left(1 + \frac{\eta^2}{3}\right)$$

For common use the shifts can be expressed in parts per million (ppm) by multiplying the right-hand side of Equation (68) by $10^6$. Equation (68) reflects the fact that the value of the isotropic chemical shift cannot be obtained from one DOR experiment if the quadrupolar shift is unknown. However, two DOR experiments at different external field strengths, which means at different Larmor frequencies, give the value of the chemical shift $\delta_{\text{CS iso}}$ and also the quadrupolar parameter $v_Q \sqrt{1 + \eta^2}/3$.

The DOR technique has been applied, first, to the $^{23}$Na resonance in sodium oxalate\textsuperscript{(54,56,62)} and later to NaNO$_2$\textsuperscript{(56,63)} to the $^{17}$O resonance in diopside\textsuperscript{(64)} and silicates\textsuperscript{(65)} and to the $^{27}$Al resonance of YAG.\textsuperscript{(63)} The majority of the DOR NMR studies was devoted to zeolites of faujasite type\textsuperscript{(66–75)} and to zeolite-like materials such as aluminophosphates,\textsuperscript{(47,66,76–86)} zirconosilicates,\textsuperscript{(87)} or sodalite.\textsuperscript{(88,89)} Other materials studied included aluminas,\textsuperscript{(90)} and aluminum borate\textsuperscript{(91)} ($^{(27)}$Al), gallium phosphate\textsuperscript{(92)} ($^{(7)}$Ga) and boron nitride\textsuperscript{(93)} ($^{(11)}$B). CP effects have been studied.\textsuperscript{(47,79)} Amoureux\textsuperscript{(84)} proposed a combination of DOR and variable-angle spinning (VAS) in which the quadrupolar shift of DOR NMR can be deduced with a simulation of the second-dimension spectra obtained with stepped values of the angle of the outer rotor with respect to the external magnetic field.

The rotation frequencies of the inner and outer rotor at present do not exceed $v_{\text{inner}} = 12$ kHz and $v_{\text{outer}} = 2$ kHz, respectively. A pneumatic unit, which is controlled by a computer, simplifies the experimental set-up and makes it safer. However, compared with the MAS technique, a more complicated set-up and stronger wear of the rotors must still be accepted for DOR experiments.

A DAS experiment was first performed independently by Chmelka et al.\textsuperscript{(64)} and Llor and Virlet.\textsuperscript{(95)} The DAS technique uses a time-dependent angle of the rotor axis, which toggles in the simple experiment between $37.38$ and $79.19^\circ$ for two equal periods of time. During the hopping time, necessary for switching the angle ($>30$ ms), the evolution of the magnetization can be reduced by means of a selective $\pi/2$ pulse pair applied at a time $t_1$ after the preparation pulse. The signal consists of a second-order quadrupolar echo with a maximum at the time $t_1$ after the last pulse. The data acquisition of the FID starting at the echo maximum gives the data in the $t_2$ domain. The two-dimensional (2-D) spectrum is obtained after a 2-D Fourier transformation with respect to $t_1$ and $t_2$. An advanced concept introduces a fourth $\pi/2$ pulse in order to retain two pathways from the $t_1$ evolution yielding a
pure absorption-phase spectrum and introduces a third angle of rotation of 54.74°, in order to correlate in two dimensions the DAS spectra with MAS spectra.\(^{96,97}\) A sideband pattern emerges if the evolution period of the 2-D DAS experiment is divided into unequal parts by RF pulses or spinner reorientation, as shown by Grandinetti et al.\(^{98}\) Fye et al.\(^{99}\) found that the switch to the magic angle after the CP step is useful for obtaining high-resolution spectra of slowly relaxing spin species. A 2-D heteronuclear correlation DAS NMR experiment with CP from \(^{23}\)Na to \(^{31}\)P was applied by Jarvie et al.\(^{100}\) in order to find connectivities between the nuclei. Wenslow and Mueller\(^{101}\) demonstrated the increased information of this so-called DAS/CP/MAS NMR experiment for the study of cation sites in glasses. Medek et al.\(^{102}\) introduced the three-dimensional dynamic-angle correlation spectroscopy (DACS), which is based on the acquisition of DAS NMR signals as a function of different initial and final spinning axes.

Two drastic limitations for the application of the DAS technique compared with the DOR technique should be noted. First, the spin–lattice relaxation time \(T_1\), which is often short for quadrupolar nuclei, has to be larger than the time period necessary for flipping the rotor axis. Second, the spin exchange due to dipolar interactions, which cannot be eliminated during the relatively long flipping time of the rotor axis, has to be sufficiently small.

### 6 MULTIPLE-QUANTUM MAGIC-ANGLE SPINNING TECHNIQUE

In 1995, Frydman and Harwood\(^{25}\) proved the feasibility of a 2-D NMR experiment that makes use of invisible multiple-quantum transitions combined with MAS to remove the anisotropy of the quadrupolar interaction. Symmetric \(p/2 \leftrightarrow -p/2\) coherences with the quantum level \(pQ\) were selected, since the corresponding powder resonances are devoid of first-order quadrupolar effects.

The phase development \(\psi(t)\) of the single or multiple-quantum coherence can be written as Equation (69):

\[
\frac{\psi(t)}{2\pi t} = \Delta \nu p + \nu_{p/2,-p/2} = \Delta \nu p + \frac{p^2}{2\pi} \frac{(3 + \eta^2)(4I + 1 - 3p^2)}{360\nu_L}
\]

\[
-\frac{p^2}{2\pi} \frac{[36(I + 1) - 17\nu^2 - 10]^2}{2\pi} \frac{(1 + \eta^2)d_{4,0}^{(4)}}{12960\nu_L}
\]

\[
+ \sqrt{36\nu^2} d_{2,0}^{(4)} \cos 2\alpha + \sqrt{27\nu^4} d_{4,0}^{(4)} \cos 4\alpha\]  

(69)

with \(\nu_{p/2,-p/2}\) from Equation (61), which is reduced under MAS conditions. The contributions from the chemical shift and from the resonance offset are included in \(\Delta \nu = \nu_{iso} - \nu_{offset}\). Equation (69) shows that by going from the multiple-quantum level \(pQ\) to the \(-1Q\) level of observation, the sign of the phase development can be inverted. Thus, the influence of the anisotropy of the second-order quadrupolar interaction is averaged out, if the times \(t_1\) and \(t_2\) spent on the quantum levels \(pQ\) and \(-1Q\), respectively, fulfill the condition in Equation (70):

\[
t_2 = \frac{36(I + 1) - 17\nu^2 - 10}{360(I + 1) - 27} t_1 = R(I, p) t_1
\]

Figure 5 Pulse sequence and coherence transfer pathway for the echo (upper way) and antiecho (lower way) consisting of two strong pulses and a weak \(z\)-filter pulse. The triple-quantum MAS pathway is shown on the lines for the nuclear spin \(I = \frac{3}{2}\).
about 180
the numerical calculations. Nonselective flip angles of
flip angles for this procedure should be taken from
be performed at the beginning of the NMR experiment
Therefore, the optimization of the pulse duration should
including the quadrupolar parameters and do not take
on the nuclear spin I and its Larmor frequency $v_L$, the
chosen coherence $pQ$ and the ratio between the
mutation frequency $v_{RF} = \gamma B_{RF}/2\pi$ and the quadrupolar
frequency $v_Q$. One conclusion is that the MQMAS
NMR spectra, which are obtained by strong pulses, do not present quantitative results with respect to the
concentration of species, since the multiple-quantum
transition efficiency is different for nuclei with different
quadrupolar frequency $v_Q$.

The calculations need a full set of NMR parameters
including the quadrupolar parameters and do not take
into consideration second-order and spinning effects.
Therefore, the optimization of the pulse duration should
be performed at the beginning of the NMR experiment
by variation of the pulse duration; and only the initial
flip angles for this procedure should be taken from
the numerical calculations. Nonselective flip angles of
about 180° and 50° for the first and second pulse,
respectively, can be used for any $I$ and $pQ$, if the Larmor
frequency is about 100 MHz and the ratio between the
quadrupolar frequency $v_Q$ and the nonselective mutation
frequency is $v_Q/v_{RF} \approx 10$. More restrictive flip angles are given in the literature$^{106,108}$ as a function of $I$ and
$pQ$. (Note that definition of the quadrupolar frequency in the literature$^{25,106,108}$ is different to the definition of Abragam$^{19}$, cf. Equation (25), which is used here: $v_{Q}^{A} = v_{Q}^{Abragam}/6$.)

An alternative approach to the solution of the multiplequantum transitions by strong pulses is to use the adiabatic
transfer by the interchange between the eigenstates 3Q
and 1Q undergoing MAS.$^{42}$ Wu et al.$^{109}$ introduced a
three-quantum magic-angle spinning (3QMAS) experiment
by rotation-induced adiabatic coherence transfer
(RIACT) for $I = \frac{1}{2}$ nuclei and applied it to the study
of sodium sites in inorganic salts. They claimed that
this method gives quantitative MQMAS NMR spectra,
since the adiabatic coherence transfer is independent of
the strength of the quadrupolar interaction. However,
theoretical calculations$^{108}$ showed that, compared with
the nonadiabatic excitation, the disturbing off-resonance
effects are more extensive for RIACT. Lim and Grey$^{110}$
performed numerical simulations of the RIACT experi-
ment as a function of asymmetry parameter and pulse
spacings and discussed the effect of very fast sample
spinning. Mildner et al.$^{111}$ demonstrated by means of
$^{17}$O studies of silicates that RIACT can be applied to
$I = \frac{1}{2}$ spins at the moderate RF field strength of $v_{RF} \approx 30$ kHz.

Ding and McDowell$^{112,113}$ claimed that a shaped first
excitation pulse would also achieve quantitative results
in nonadiabatic 3QMAS NMR experiments and that
properly shaped pulses can also reduce the requirements
on the RF power and sample spinning speeds. The
superior excitation of triple-quantum coherences by
composite pulse schemes was also shown by Marinelli
et al.$^{114}$

Kentgens and Verhagen$^{32}$ showed that DFSs are very
efficient for the conversion of triple- to single-
quantum coherence in MQMAS spectroscopy. Goldbouurt
et al.$^{115}$ used instead fast radiofrequency amplitude
modulation (FAM) in the version FAM and FAM1
for $I = \frac{1}{2}$ and $I = \frac{5}{2}$ nuclei, respectively, and obtained
a substantial intensity and resolution enhancement of the
signal over the commonly used MQMAS pulse schemes. A very strong RF field, no resonance offset
and a high spinning rate, if possible 30 kHz as shown by
Rocha$^{116}$ are still the requirements for most MQMAS
experiments.

For both the nonadiabatic and adiabatic MQMAS
experiments described above, the selection of desired
multiple-quantum coherences is done by phase
cycling$^{111,117}$ Methods of hypercomplex or time-
proportional phase increment (TPPI) 2-D Fourier
transformation$^{109}$ are used for the acquisition of real and imaginary part with respect to the
$\tau_1/v_1$ dimension. Fyfe et al.$^{119}$ used pulsed field
gadients instead of phase cycling. The advantage is the
simplification of the MQMAS pulse program, which
allows the implementation of correlation experiments.
However, the insertion of the field gradient coil reduces
the maximum achievable RF power.

A shearing transform of the experimentally obtained
2-D spectrum, which aligns anisotropic ridges parallel
to the $v_2$ axis in such a way that the isotropic dimen-
sion can be displayed along the $v_1$ axis, is described
below. Brown et al.$^{104,120,121}$ introduced an experiment
with an additional pulse called split-$\tau_1$ MQMAS that
is pure adsorptive and includes the shearing ratio
into the pulse program so that anisotropic ridges
due to shearing procedure. The two signals in the spectra are spectra of the zeolite Na-ZSM-5 before and after the chemical shift, \( \delta \), the total shift is a superposition of the isotropic part of Equation (69). Without resonance offset, the total shift is a superposition of the isotropic part of the chemical shift, \( \sigma_{iso} v_L \), and the isotropic part of the quadrupolar shift, \( \nu_{isoQ} \) (Equation 71):

\[
\nu_{isoQ} = \sigma_{iso} v_L p + \nu_{isoQ} = \sigma_{iso} v_L p + \frac{p\nu^2(Q)(3 + \eta^2)[4I(I + 1) - 3p^2]}{360v_L} \tag{71}
\]

Equation (71) can be transformed into relative units (ppm) by multiplication by \( 10^6/(-p\nu_L) \). The value \(-p\nu_L\) describes the apparent Larmor frequency and includes the real Larmor frequency for \( p = -1 \). For the \( \nu_1 \) axis (before shearing) and for the \( \nu_2 \) axis, we have Equations (72) and (73), respectively:

\[
\delta_1 = \delta_{CS iso} + \delta_{Q iso} = \delta_{CS iso} - \frac{\nu^2(Q)(3 + \eta^2)[4I(I + 1) - 3p^2]}{360v_L} \tag{72}
\]

\[
\delta_2 = \delta_{CS iso} + \delta_{Q iso} = \delta_{CS iso} - \frac{\nu^2(Q)(3 + \eta^2)[4I(I + 1) - 3]}{360v_L} \tag{73}
\]

Equation (73) describes the shift \( \delta_2 \) of the center of gravity of the anisotropic ridge, which is not influenced by the shearing transformation. The coordinate \( \delta_{Q shearing} \) after the transformation is given by Equation (74):

\[
\delta_{Q shearing} = \delta_{CS iso} + \delta_{Q iso} = \delta_{CS iso} + \frac{\nu^2(Q)(3 + \eta^2)[4I(I + 1) - 3]}{612v_L} \tag{74}
\]

It can be seen that after shearing the quadrupolar shift becomes always positive and independent of \( p \). Comparison of Equation (74) with Equation (73) gives the slope of two special lines in the sheared 2-D spectrum. One line with slope 1, which is denoted CS in Figure 6, describes the variable isotropic chemical shift in the case of zero quadrupolar shift. Only one line CS exists and crosses the coordinates \((0, 0)\). Lines Q with slope \(-10/17\) describe variable quadrupolar shifts at one value \( \delta_{CS iso} \), which is given by the crossing of line Q with line CS. The shift difference between this crossing point and the center of gravity of a signal gives the corresponding quadrupolar shift \( \delta_{Q iso} \). One-dimensional anisotropic slices A are obtained from the 2-D spectrum. These slices can be fit by a line-shape simulation, which gives values for \( \nu_Q \) and \( \eta \), whereas \( \delta_{Q iso} \) is a measure of \( \nu_Q \sqrt{1 + \eta^2}/3 \). The quadrupolar parameter obtained from the 2-D spectrum can then be used for a simulation of the single-quantum MAS NMR spectrum. This procedure yields correct information about the relative concentration of the various species giving rise to the corresponding signals. The program REGULAR, which was developed by Delevoye, takes full advantage of the information included in the 2-D MQMAS NMR spectrum and thereby

![Figure 6](image_url)

**Figure 6** 2-D $^{17}$O 3QMAS NMR spectra of the zeolite Na-ZSM-5 (a) after the 2-D Fourier transformation and (b) after the following shearing transformation. The two signals were assigned to SiOSi and SiOAl fragments with concentrations of 80 and 20%, \( \delta = 40 \) and 30 ppm, \( C_{iso} = 5.3 \) and 3.5 MHz, \( \eta = 0.12 \) and 0.29, respectively. (The figure was provided by Ulf Pingel.)

are parallel to the \( \nu_2 \) axis after the 2-D Fourier transformation.

Figure 6(a) and (b) shows the 2-D $^{17}$O 3QMAS NMR spectra of the zeolite Na-ZSM-5 before and after the shearing procedure. The two signals in the spectra are due to Si–O–Si and Si–O–Al bonds. The spectra demonstrate how the projection on the \( \nu_1 \) axis is changed by the shearing. The analytical treatment starts from the isotropic part of Equation (69). Without resonance offset, the total shift is a superposition of the isotropic part of the chemical shift, \( \sigma_{iso} v_L \), and the isotropic part of the
quantifies the distribution of nucleus surroundings also in badly crystallized and amorphous materials. A 2-D result is obtained which represents quadrupolar constants versus isotropic chemical shifts with correct relative intensities. Scaling and labeling of the isotropic axis (ν1 axis after shearing) was considered in detail by Man.\(^{(125)}\)

The residual line width of the MQMAS NMR spectra is a matter of current research. Wu and Wasylishen\(^{(124)}\) showed that the heteronuclear dipolar interaction between two nuclei does not cause residual dipolar couplings in MQMAS NMR experiments.

The spinning sidebands in the multiple-quantum dimension are a common feature of dipolar-coupled spin \(I = \frac{1}{2}\) and half-integer quadrupolar systems. Both cases were considered by Friedrich et al.\(^{(125)}\) The case of half-integer spins is the subject of various studies.\(^{(126–129)}\) Spinning sidebands arise even in the absence of explicit time modulations of any spin interactions, due to orientation and time dependence characterizing the multiple- to single-quantum conversion process, as shown by Marinelli and Frydman.\(^{(126)}\) The sidebands cause signal loss and misinterpretation of spectra. Rotor synchronization, which means setting the evolution dwell time equal to the rotation period, is useful for suppressing these spinning sidebands.\(^{(130)}\) However, it limits the spectral width of the multiple-quantum dimension to the rotation frequency. This drawback increases on going from triple- to quintuple-quantum transitions.

Several combinations of MQMAS with other NMR techniques have been successfully applied. Vosegaard et al.\(^{(131)}\) added the Carr–Purcell–Meiboom–Gill (CPMG) pulse sequence to the MQMAS pulse program, in order to improve the sensitivity by splitting the line shape in the ν2 dimension into manifolds of spinning sidebands. High-power \(^1\)H decoupling improves the resolution in both dimensions.\(^{(132,133)}\) Lacassagne et al.\(^{(134)}\) demonstrated improved resolution for strong heteronuclear coupling by applying composite decoupling schemes during the evolution and acquisition time. Wang et al.\(^{(135)}\) provided chemical shift anisotropy data by multiple-quantum variable-angle spinning (MQVAS). CP provides information about connectivities.\(^{(136–139)}\) REDOR\(^{(139–141)}\) and heteronuclear chemical shift correlation (HETCOR)\(^{(138,142)}\) were also applied in addition to MQMAS. The most difficult combination, DOR in addition to MQMAS, was presented by Samoson et al.\(^{(143,144)}\) The advantage of multiple-quantum double-rotation (MQDOR) compared with MQMAS is that the need for simulations is avoided.\(^{(143)}\) However, although in principle most informative, experimental difficulties and low multi-quantum conversion efficiency make the applicability of the MQDOR technique currently relatively limited.\(^{(144)}\)

MQMAS NMR studies have been carried out on all half-integer quadrupolar spins from \(I = \frac{1}{2}\) to \(I = \frac{9}{2}\) \(^{125}\)\(^{106}\)\(^{}\). The nucleus \(^{59}\)Co (\(I = \frac{7}{2}\)) in nitrogen compounds was studied to show the interplay between the chemical shift anisotropy and the quadrupolar interaction. However, the majority of the studies were focused on the two nuclei \(^{27}\)Al (\(I = \frac{5}{2}\)) and \(^{23}\)Na (\(I = \frac{5}{2}\)). Two examples are the study of the aluminum coordination in \(\text{SrAl}_2\text{O}_19\) by Jansen et al.\(^{(145)}\) and the study of sodium cations in dehydrated zeolites by Hunger et al.\(^{(146)}\) Zeolites, zeolite-like materials and glasses\(^{(147,148)}\) have been investigated in many studies.

### 7 NUTATION TECHNIQUE

Nutation NMR spectroscopy represents a 2-D experiment: a strong RF field is irradiated during the evolution period \(t_1\), and the FID is observed during the detection period \(t_2\). In the rotating frame, the spins nutate (precess) around the strong RF field with specific nutation frequencies \(w_{1f}\); here the subscript 1 denotes the frequency \(I_1\) in the 2-D spectrum corresponding to the Fourier transform with respect to \(t_1\) and should not be confused with \(w_{1f} = \gamma B_{1f}\) which is a constant for the 2-D experiment. The original one-dimensional nutation experiment of Torrey\(^{(149)}\) uses only one point of the FID.

Samoson and Lippmaa\(^{(150,151)}\) introduced 2-D nutation NMR studies of half-integer quadrupolar nuclei. A corresponding one-dimensional experiment was performed by Fenzke et al.\(^{(152)}\) For quadrupolar nuclei, the effective nutation frequencies \(w_{1f}\) depend on the strength of the quadrupolar interaction, as has been shown in section 3. If \(w_Q \ll w_{1f}\), then the transverse magnetization responds to the RF pulse like spin-\(\frac{1}{2}\) nuclei, thus \(w_1 = w_{1f}\). If \(w_Q \gg 10w_{1f}\), the central transition can be treated as a two-level system and an effective nutation frequency is expected, that is, increased by a factor \(I + \frac{1}{2}\), i.e. \(w_1 = (I + \frac{1}{2})w_{1f}\) (cf. Equation 39). For the intermediate case, \(0.1 < w_Q/w_{1f} < 100\), the nutation spectra are complicated because of the influence of the partly excited outer satellite transitions.

Nutation spectra can be calculated using numerical procedures or by means of an analytical description which is the more complicated the larger the spin quantum number. The powder average, which produces complicated nutation spectra, is necessary, in order to deduce quadrupolar parameters from the spectra and to compare the experimental spectrum with a set of calculated spectra. An analytical approach was found for \(I = \frac{1}{2}\) \(^{(153–156)}\) for \(I = \frac{3}{2}\) \(^{(157,158)}\) and for \(I = \frac{5}{2}\) \(^{(159,160)}\) yielding \((I + \frac{1}{2})^2\) different nutation frequencies of the central transition. Each frequency gives rise to a powder
pattern, and $2I$ of the $(I + \frac{1}{2})^2$ frequencies are dominant. Calculated line shapes of nutation spectra can be found in papers by Kentgens et al.\(^{161,162}\) and in a review by Freude and Haase.\(^{9}\) The latter reviews the quadrupolar nutation literature from 1983 to 1992 (about 40 papers), including experimental aspects such as inhomogeneity of the RF field, resonance offset, influence of MAS, spin–lattice relaxation, spin–spin relaxation in the rotating frame and some advanced concepts in nutation spectroscopy. Since 1993, another 15 papers were published, among them recent work about nutation MAS NMR by Ding and McDowell.\(^{146,163}\)

The most advanced concept, the off-resonance nutation NMR of half-integer nuclei, was introduced by Kentgens.\(^{164}\) The large resonance offset, $\nu_{\text{offset}} \gg \nu_{\text{rf}}$, during the irradiation causes an evolution of the spin system in the effective field, $B_{\text{eff}} = B_{\text{offset}} + B_{\text{rf}}$, whereas the signal is as usually observed in resonance. The off-resonance technique extends the range of applicability at the signal is as usually observed in resonance. The off-resonance nutation spectra can be found in the effective field, $\text{signal}$ in the effective field, $B_{\text{eff}} = B_{\text{offset}} + B_{\text{rf}}$, whereas the signal is as usually observed in resonance. The off-resonance technique extends the range of applicability at the signal is as usually observed in resonance.

\(8\) ECHO TECHNIQUES

Echo techniques provide two data sets in the NMR time domain. First, the echo decay dependence on the time $t_2$ starting from zero at the maximum of the echo gives similar information to the initial FID after the preparation pulse, but the loss of signal during the ring down of the probe and the recovery of the receiver immediately after the pulse is overcome in the echo technique. Second, by varying the pulse distance $t_1$ between the preparation pulse and the refocusing second pulse, the resulting envelope of the echo decay gives additional information about the spin system. The refocusing effect of a second pulse after a preceding $\pi/2$ pulse for an interaction that is proportional to $I_z$ is called the Hahn echo. The original experiment by Hahn\(^{165}\) was performed with identical phase incoherent pulses in an inhomogeneous external magnetic field. The term Hahn echo is now in use for the spin-echo (after $\pi/2 - t_1 - \pi - t_1$) of spin-$\frac{1}{2}$ nuclei or of quadrupolar nuclei with half-integer spins, if the central transition is selectively excited.

However, the quadrupolar interaction strongly influences the formation of an echo: homonuclear dipolar interactions which mainly cause the decay of the spin-echo amplitude become less effective since spin-flipping between different transitions is forbidden. Owing to the nature of the quadrupolar coupling, which is to first order proportional to $I_z^2$, refocusing is not complete. Also, the limited range of excitation for very broad lines of powder samples causes complicated spin-echo behavior.

Echo studies on quadrupolar nuclei with half-integer spin (for integer spin, see section 9) were reviewed by Freude and Haase,\(^{9}\) beginning with the pioneering work of Das and Saha\(^{6}\) in 1955 up to the publications in 1993, e.g. Haase and Oldfield.\(^{160}\) Several cases, which can be mainly divided into nonselective and selective excitation, were considered, as follows.\(^{9}\)

Nonselective and hard pulses without dipole interaction cause several echoes at times $k \times t_1$ with $k = \frac{1}{2}, 1, \frac{3}{2}$ and $k = \frac{1}{2}, 1, \frac{3}{2}, 2, 3$ for $I = \frac{3}{2}$ and $I = \frac{5}{2}$, respectively. Some of these are forbidden echoes: $k = \frac{1}{2}, \frac{3}{2}$ and $k = \frac{3}{2}, 3$ for $I = \frac{5}{2}$ and $I = \frac{7}{2}$, respectively. On going from hard to soft pulses (cf. section 3), the influence of the quadrupolar interaction during the pulse has to be considered and the selection rule is changed. Then also the forbidden echoes can be observed. The consideration of dipole interaction for first-order quadrupolar echoes can be divided into two parts. First, the heteronuclear dipole interaction, which is proportional to $I_I S_S$, can generally be removed by the application of a second $\pi$-pulse. However, strong coupling among the $S$ spins, and also a short spin–lattice relaxation time of the $S$ spins, can destroy the formation of the $I$ spin echo. Second, if the homonuclear dipolar interaction is large compared with the quadrupolar interaction, $||D|| \gg ||Q||$, its influence is essentially the same as for spin-$\frac{1}{2}$ nuclei. If the quadrupolar interaction is large compared with the dipolar interaction, $||Q|| \gg ||D||$, spin exchange due to homonuclear dipole interaction between adjacent levels can be considered as being suppressed completely and the echo decay can be investigated by selective excitation of each transition, separately.

$||Q|| \gg ||D||$ and $||Q|| \gg ||D|| \approx ||D||$ denote the cases of selective excitation of a single transition without and with dipole interaction, respectively. For powder we can mainly excite the central transition, and for single crystals we can tune to any transition and describe it by the reduced spin-$\frac{1}{2}$ formalism.\(^{19}\) Without the dipole interaction an echo is observed at the time $t_1$ after the $\pi$ pulse in full analogy with spin-$\frac{1}{2}$ nuclei subjected to an inhomogeneous interaction. Since the calculation of the spin-echo amplitude in the presence of dipolar interactions can be complicated,
the spin-echo decay has been discussed by Haase and Oldfield\(^{166}\) in terms of the second moment spin-echo decay (cf. section 5.2.5 in Freude and Haase\(^{9\text{a}}\)).

Echo techniques in combination with coherence selection (multiple-quantum filter) reduce the overlap of signals of quadrupolar nuclei in anisotropic soft matter, as demonstrated by Furo and Halle.\(^{167,168}\) Recent progress in this field was presented by Eliav et al.\(^{169–172}\) The use of echoes for the editing of \(^{27}\)Al MAS NMR spectra of zeolite catalysts was shown by Schmitt et al.\(^{173}\) The connection between all NMR interactions (except the homonuclear dipole interaction) and the optimum experimental conditions for the avoidance of spectral distortions was described by Dumazy et al.\(^{174}\)

The leading authority in the field of quadrupolar echoes is Pascal Man, who has published more than 10 papers on this topic during the last decade. Most of them are discussed in recent publications.\(^{175–177}\)

The CPMG\(^{178,179}\) pulse sequence \(\pi/2, (t_1, \pi_y, t_1)_n\) can be considered as an advanced concept of the Hahn echo. Larsen et al. reconsidered the quadrupolar version of CPMG (QCPMG) without MAS\(^{180}\) and with MAS.\(^{181}\) For MQMAS NMR and \(^2\)H NMR, see sections 6 and 9, respectively. More than one order of magnitude can be gained in sensitivity by the application of this QCPMG technique.

9 \(^2\)H NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

\(^2\)H is the most important NMR isotope with an integer nuclear spin \(I = 1\), rather seldom \(^6\)Li and \(^{14}\)N NMR studies can be found in the literature. About 10% of the solid-state NMR studies of quadrupolar nuclei concern deuteron magnetic resonance spectroscopy, which is a powerful technique for investigating molecular structure and dynamics. This small section does not correspond to the importance of the deuteron NMR, especially for the study of dynamics. The textbook by Schmidt-Rohr and Spiess, \textit{Multidimensional Solid-state NMR and Polymers}\(^{182}\) and the reviews by Hoatson and Vold, \(^2\)H-NMR Spectroscopy of Solids and Liquid Crystals\(^{11}\) and Ulrich and Grage, \(^2\)H NMR (Solid-state NMR of Polymers)\(^{14}\) demonstrate the wealth of modern applications of solid-state \(^2\)H NMR.

The experimental techniques for nuclei with the spin \(I = 1\) are different to the techniques for nuclei having half-integer spins mainly for one reason, that no central transition exists. There are only two transitions for the magnetic quantum number \(m_I = -1 \leftrightarrow 0\) and \(0 \leftrightarrow 1\). They cause a line splitting that is symmetric with respect to the Larmor frequency if the quadrupolar interaction is considered in first-order perturbation theory with respect to the Zeeman interaction (cf. Equation 40). From Equation (41) it follows that the second-order shifts for both transitions are identical. Thus, the splitting between the two lines (difference frequency), which is the experimentally observed parameter in studies of single crystals, is not influenced by the second-order quadrupolar interaction.

Equations (40) and (41) can be used for nuclei with the spin \(I = 1\), but the quadrupolar frequency should be substituted by the quadrupolar coupling constant using \(v_Q = 3C_{\text{qcc}}/2\). The definition of the quadrupolar frequency for half-integer spins in Equations (25) and (26) is rather unusual for integer spins. The use of the quadrupolar coupling constant \(C_{\text{qcc}}\) after Equation (24) is commonly accepted, but for integer spins no rotational consistency exists with respect to the quadrupolar frequency \(v_Q\).

The asymmetry parameter \(\eta\) (cf. Equations 19 and 20), is relatively small for the majority of the \(^2\)H NMR studies due to a rotation symmetry of the hydrogen bonding. The theoretical powder line shape of nuclei with \(I = 1\) and \(\eta = 0\) is equal to the line shape of isolated pairs of nuclei with the spin \(I = \frac{1}{2}\). Therefore, the typical \(^2\)H NMR pattern of the so-called static powder (no sample rotation and no internal rotation) is often referred to as the Pake powder pattern. Pake in 1948 studied the \(^2\)H NMR spectra of gypsum and discussed the angular dependence of the doublets in the spectra of a single crystal and the powder pattern in the spectrum of a powder sample as well.\(^{182}\)

The splitting of lines of single crystals or the full width of powder patterns reach values up to 300 kHz. From \(\delta v_{1/2} \approx 0.886/\tau\) (cf. Equations 32–34), it follows that a duration \(\tau \leq 2\ \mu s\) for the \(\pi/2\) pulse is necessary, in order to obtain a quite uniform excitation of the whole spectrum. In addition to the need for high RF power, an echo pulse sequence must be applied in order to overcome the dead time problem of the receiver. A simple pulse sequence consisting of two \(\pi/2\) pulses with a pulse duration of \(2\ \mu s\) and a pulse separation of \(20\ \mu s\) with phase cycling (the phase of the first pulse is cycled with respect to the synthesizer, and in addition the phase of the second pulse is cycled with respect to the first pulse) is the standard for solid-state \(^2\)H NMR experiments. The pulse separation must be adjusted to one rotation period if MAS is applied. Hoatson discussed the broadband composite excitation sequences\(^{183}\) and the Hadamard pulse excitation\(^{184,185}\) for detecting quadrupolar order in \(^2\)H NMR. Noise spectroscopy provides broad-bandwidth excitation with minimal applied RF field strengths. The state-of-the-art for applications to the \(^2\)H solid-state NMR was described by Yang et al.\(^{186,187}\) More detailed consideration of the quadrupolar echo in \(^2\)H NMR can be found in the review by Hoatson and Vold,\(^{11}\) Chapter 2.2, and the references.
Deuterium labels are introduced synthetically or by a postsynthesis treatment of the material. The labeled hydrogen segment can be investigated in terms of its specific structural and dynamic properties. The natural abundance of $^2$H is only 150 ppm. The relative sensitivity of naturally abundant $^2$H with respect to the $^1$H NMR sensitivity at constant external field is only 1.5 ppm. Nevertheless, natural abundance high-resolution solid-state $^2$H NMR investigations can be performed if MAS, high-power $^1$H decoupling and $^1$H–$^2$H CP are used.$^{190,191}$

$^1$H–$^2$H CP effects in single- and double-quantum (DQ) transitions of the $^2$H NMR were theoretically and experimentally investigated by Vega et al.$^{192}$ in 1980. There are two reasons why CP is rarely used in the solid-state $^1$H NMR: the maximum increase in the $^1$H NMR intensity due to the CP from $^1$H spins is given by the gyromagnetic ratio $\gamma_H/\gamma_D \approx 6.5$ for infinitely diluted $^2$H nuclei. This value decreases if the concentration of $^2$H nuclei increases with the deuteron enrichment. However, the increasing level of deuteration increases the $^2$H NMR intensity more effectively. The second point is that the high-power decoupling of the protons close to the deuterons causes some problems. However, $^1$H–$^2$H CP is invaluable for the investigation of the interfaces of the deuterated segments, e.g. in polymer blends. Ba et al.$^{193}$ proposed a quadrupolar echo double resonance (QEDOR) and a solid echo double resonance (SOLEDOR) NMR experiment in order to provide information about deuteron–proton distances. A new theoretical model that describes CPMAS experiments for abundant $I = \frac{1}{2}$ spins coupled to a single spin $S = 1$ was presented by Marks et al.$^{194}$ Gan and Robyr$^{195}$ described a new 2-D CPMAS experiment with a three-pulse sequence for the determination of the relative orientation between $^2$H quadrupolar coupling tensors.

The MAS technique for powder materials offers a more sensitive technique (compared with the quadrupolar echo technique) and the opportunity for an accurate measurement of the chemical shift.$^{196}$ A simple variation of the processing procedure of the FID, which is obtained in a one-pulse experiment, gives a 2-D spectrum with quadrupolar pattern in one dimension and the isotropic chemical shift in the other dimension.$^{197,198}$ The 2-D data set in the time domain can be constructed from the one-dimensional set, which should be acquired with a dwell time $\tau_{\text{dwell}}$ and a rotation frequency $\nu_{\text{rot}}$ in the order of magnitude of 1 ms and 5 kHz, respectively. $N = (2\nu_{\text{rot}}\tau_{\text{dwell}})^{-1}$ points with the time distance of $2\tau_{\text{dwell}}$

starting at the top of each rotational echo define the $t_2$ domain, and the increments of $t_1$ as the rotation period $1/\nu_{\text{rot}}$ give the $t_1$ domain. Spaniol et al.$^{199}$ recently used a 2-D $^2$H MAS NMR experiment for the separation of paramagnetic and quadrupolar interactions.

Quadrupolar effects do not shift (or broaden in the case of powder) the signals arising from DQ transitions. Therefore, 2-D $^2$H DQ NMR spectra provide information about the chemical shift of the deuterons.$^{200}$ Advantages of the MAS NMR technique compared with the DQ NMR technique are the higher sensitivity of the single-quantum compared with the DQ transition and the higher sensitivity of the MAS technique compared with the static echo technique. Multiple-quantum effects in combination with MAS are less often used for $^2$H nuclei$^{201–203}$ compared with nuclei with half-integer spin (cf. section 6). Chandrakumar et al.$^{203}$ use a four-pulse experiment (QUADSHIFT) with a $t_1$ interval in the middle (which is incremented by the rotation period) in order to obtain chemical shift values and quadrupolar parameters from DQ coherences under MAS conditions [see also Chandrakumar$^{13}$]. $^2$H MAS NMR imaging experiments were described by Blümich.$^{188}$

Deuterium NMR spectroscopy of single-crystal systems is an active field of research. The original approach of Volkoff et al.$^{14,5}$ is still in use, in order to obtain the quadrupolar parameters from the angular dependence of the line splitting, and new aspects were found and applied by Haebeleren et al.$^{204,205}$ The work up until 1994 is reviewed by Chandrakumar$^{13}$ and recent results are also available.$^{204,205}$ The ordering behavior at the phase transition in single crystals of betaine phosphate and betaine phosphate has also been studied by one-dimensional and 2-D $^2$H NMR.$^{206}$

The majority of $^2$H NMR studies concern molecular dynamics. Many polymer systems are studied, because $^2$H NMR is ideally suited to explore molecular motions in polymers.$^{14}$ There is a wide range of timescales for the correlation times that are accessible by various methods: $10^2–10^4$ s (2-D exchange spectroscopy), $10^2–10^5$ s (selective inversion), $10^4–10^5$ s (line-shape analysis), $10^5–10^6$ s ($T_2$ anisotropy), $10^8–10^{12}$ s ($T_{1Z}$ anisotropy) and $10–10^{12}$ s ($T_{1\Omega}$ anisotropy).$^{11}$ For exchange spectroscopy we refer to the textbook by Schmidt-Rohr and Spiess.$^{18}$ The introduction of multi-dimensional exchange experiments by Spiess et al. gave rise to strong developments in this field. Kubo et al.$^{207}$ recently combined deuterium selective-excitation exchange spectroscopy with the Hadamard method for the measurement of reorientation rates. The technique of selective inversion is based on the selective excitation or the so-called hole burning that has been well known in NMR from the very beginning.$^{208}$ Recent applications to $^2$H NMR have been reviewed by Hoatson and Vold.$^{11}$
Table 5  Quadrupolar coupling constant $C_{QCC} = e'qQ/h$, the asymmetry parameter $\eta$ and the isotropic value of the chemical shift $\delta$ (referred to 1.0 M AlCl$_3$-6H$_2$O) for the $^{27}$Al NMR of powder compounds at ambient temperature$^a$

If the quadrupolar echo decay ($\pi/2, t_1, \pi/2, t_1, t_2$) is monitored as a 2-D data set, the doubly Fourier transformed 2-D spectrum can be influenced by a slow motion. Schleicher et al.$^{(209)}$ applied this technique for the observation of dynamics in alanine. Müller et al.$^{(210)}$ used a multiple-pulse quadrupolar echo sequence, in order to obtain information about the chemical exchange. For other examples, including the influence of dynamics on the longitudinal relaxation time in the Zeeman reservoir $T_{1Z}$ or the relaxation time in the quadrupolar reservoir $T_{1Q}$, see Vold et al.$^{(11,211)}$

Larsen et al.$^{(212)}$ applied the CPMG experiment to deuterons ($^2$H QCPMG) and thereby enhanced the sensitivity by about one order of magnitude and the dynamic range by two orders of magnitude.

Dynamic experiments were mainly performed with nonrotating samples. However, dynamic $^2$H MAS NMR is now in progress. Weintraub and Veiga$^{(213)}$ studied dimethyl sulfone by MAS and off-MAS techniques. Kristensen et al. investigated multiaxial dynamics$^{(214)}$ and effects of restricted rotational diffusion.$^{(215)}$

10 SURVEY OF NUCLEAR MAGNETIC RESONANCE PARAMETERS FOR SELECTED COMPOUNDS

Collections of electric field gradient and chemical shift data for the most commonly studied quadrupolar nuclei with half-integer spins $^{27}$Al, $^{23}$Na and $^{17}$O are presented in Tables 5, 6 and 7, respectively. For

1 INTRODUCTION

Most nuclei in the periodic table have a spin $I$ larger than $\frac{1}{2}$. These spins are called quadrupole spins and they are sensitive to the EFG generated by their surroundings. The coupling of the nuclear electric quadrupole moment $eQ$ (a property of the nucleus) with an EFG (a property of the sample) is called the quadrupole interaction.$^{11-31}$ Nuclei with quadrupole spins are extensively used to probe static and dynamic phenomena accompanying reversible phase transitions in solids.$^{14-6}$ This article focuses on half-integer quadrupole spins ($I = \frac{3}{2}, \frac{5}{2}, \frac{7}{2}, \text{and} \frac{9}{2}$) in NMR experiments; that is, the interaction of the spin system with the Zeeman field $B_0$ (the strong static magnetic field) is much larger than the quadrupole interaction.$^{77}$ Under these conditions, we consider the first two expansion terms of this interaction, namely the first- and second-order quadrupole interactions.

There are two ways to investigate the effects of an interaction in NMR:

- Studying the frequency-domain response of the spin system, which deals with transition frequencies between two energy levels and therefore the line positions, line shifts, and line shapes in the spectrum.
- Predicting the time-domain response of the spin system, namely the signal intensities, positions and amplitudes of echoes by using the density operator formalism.

Two-dimensional (2-D) NMR experiments are based on the time-domain response of the spin system to specific sequences, designed in such a way that the desired information is clearly shown in 2-D spectra.$^{8-10}$

The main effects of the quadrupole interaction in the frequency domain are gathered in section 2 but are not developed because excellent review articles are available in the Encyclopedia of Nuclear Magnetic Resonance.$^{11,12}$ Expressions for the second-order quadrupole shift of the central line under static conditions, and for variable- and magic-angle spinning (MAS) are provided, together with the procedure for simulating powder patterns. As the spectra are the Fourier transforms of time-domain signals, which depend on the experimental parameters such as the strength of $B_0$, that of the RF field $B_1$, the pulse durations, the pulse separation, or the relative

---

Nuclear magnetic resonance (NMR) spectroscopy is continually finding new applications. It enables the local symmetry to be probed at the atomic scale using the nuclear spins $I$ of the compound under investigation. The nuclear spin is either a half-integer (or odd) number or an integer (or even) number. The nuclei in the periodic table can be divided into two parts – spin-$\frac{1}{2}$ nuclei and spin larger than $\frac{1}{2}$ nuclei. The spin larger than $\frac{1}{2}$ nuclei are called quadrupole nuclei because they possess an electric quadrupole moment which interacts with the electric-field gradient (EFG) generated by its surroundings. By extension, their spins are called quadrupole spins. Spin-$\frac{1}{2}$ nuclei are not sensitive to the EFG. Of the nuclei that possess a spin, 6% have integer quadrupole spins and 66% have half-integer quadrupole spins.

This article focuses on the half-integer quadrupole spins ($I = \frac{3}{2}, \frac{5}{2}, \frac{7}{2}, \text{and} \frac{9}{2}$) in single crystals and in powder compounds. Most of these spins are observable. As they are multi-energy-level systems (the number of energy levels is $2I + 1$), multiple quantum (MQ) transitions occur during excitation of the spin system by a radiofrequency (RF) pulse sequence. As a result, quantum mechanical concepts are needed for an understanding of the spin dynamics and for interpretation of the results. In particular, the choice of pulse sequence and the experimental conditions, such as pulse duration, pulse strength, and phase cycling in the pulse sequence, depend on the strength of the EFG surrounding the nuclear spin.
phase of the RF pulses, understanding of the effects of these parameters enables the undistorted line shapes to be obtained.

Section 3 deals with the time-domain response of the spin system excited by one- and two-pulse sequences that include Solomon echoes \(^{(1,13)}\) and Hahn echoes. \(^{(14)}\) Section 3.1, which focuses on one-pulse and 2-D nutation experiments, gives the meanings of the elements of the density matrix at the end of an RF pulse. The properties of these elements are crucial for an understanding of echoes in NMR. Nonselective (or hard) pulse excitation, and selective excitation of the spin system are presented to establish the experimental conditions for quantification of the spin population. For this purpose, the nature of a line (only the central line or the full spectrum) must be determined by a one-dimensional (1-D) nutation experiment. Section 3.2 presents a composite-pulse sequence that cancels spurious signals generated by the NMR probe when low-gyromagnetic-ratio nuclei are studied in a Zeeman field \(B_0\). Quantification of the spin population with this composite-pulse sequence is not possible. The numerical procedures for calculating the line intensity from single-pulse and composite-pulse sequences are given.

Section 3.3 presents a method for obtaining the two quadrupole parameters (the quadrupole coupling constant and the asymmetry parameter) from a featureless central-transition line shape by using a two-pulse sequence with a short pulse separation. This method is an extension of the 1-D nutation experiment, which is based on the fact that the variation of the line intensity versus a pulse duration depends on the ratio of the quadrupole coupling \(w_Q\) to the strength \(w_{RF}\) of the RF field \(B_1\). Furthermore, knowledge of the two quadrupole parameters allows the true isotropic chemical shift of a line to be determined. The latter is related to bond angle in solids. \(^{(15)}\)

The broad powder pattern is distorted by the dead time of the receiver following an RF pulse. The usual way to overcome this problem is to apply a spin echo sequence. However, there is a subtle but important difference between Solomon echoes and Hahn echoes. Extensive examples are provided for supporting predictions. For simplicity mainly spins \(I = \frac{3}{2}\) and \(\frac{5}{2}\) are discussed because they represent the most-studied nuclei. Section 3.4 discusses Solomon echoes with respect to the excitation conditions, namely nonselective (or hard-pulse) excitation, and soft-pulse excitation. These echoes are satellite-transition signals only, because the delay separating the two RF pulses is much shorter than the duration of the free-induction decay (FID) of the central transition. \(^{(16)}\) A numerical procedure is proposed to calculate the amplitudes of Solomon echoes, allowing the conditions for their observation to be optimized.

Quantification of the spin population is not possible with satellite-transition signals.

For Hahn echoes, which are discussed in section 3.5, the pulse separation is larger than the duration of the central-transition FID; both central-transition and satellite-transition echoes are observed. \(^{(17,18)}\) As a result of the spin–spin relaxation, Hahn echo amplitudes are much smaller than Solomon echo amplitudes. The various excitation conditions are also reviewed to deduce the conditions for quantifying the spin population. Hahn echo sequences also cancel spurious signals. A numerical procedure is proposed to predict the echo amplitudes. Section 3.5.7 discusses Hahn echoes in rapidly rotating samples. Finally, a 2-D multiple quantum/magic-angle spinning (MQ/MAS) experiment is reviewed in section 3.5.8. Emphases are on the various conventions for scaling and labeling the high-resolution axis in a 2-D sheared spectrum.

2 FREQUENCY-DOMAIN RESPONSE

2.1 Quadrupole Interaction

In its principal-axis system (PAS), the EFG tensor \(V\) is given by Equation (1):

\[
V = \begin{pmatrix}
V_{XX} & 0 & 0 \\
0 & V_{YY} & 0 \\
0 & 0 & V_{ZZ}
\end{pmatrix}
\]  

As the Laplace equation is valid, \(V_{XX} + V_{YY} + V_{ZZ} = 0\), two new parameters are used: the largest component \(eq\) (Equation 2) and the asymmetry parameter \(\eta\) (Equation 3),

\[
eq \frac{V_{ZZ}}{V_{XX} - V_{YY}} \tag{2}
\]

\[
\eta = \frac{V_{XX} - V_{YY}}{V_{ZZ}} \tag{3}
\]

with \(0 \leq \eta \leq 1\). If necessary, the axes of the EFG tensor are relabeled to satisfy Equations (2) and (3). The definition of \(\eta\) is not unique. \(^{(1)}\)

In NMR, the quadrupole interaction is treated as a weak perturbation of the Zeeman interaction (Equation 4),

\[
H_Z = -w_L I_z \tag{4}
\]

the coupling of the nuclear spin \(I\) with the Zeeman field \(B_0\). The Larmor frequency (Equation 5) is

\[
w_L = \gamma B_0 \tag{5}
\]

which is a positive number if the gyromagnetic ratio \(\gamma\) is positive. The standard approach mainly considers the
QUADRUPOLE COUPLINGS IN NUCLEAR MAGNETIC RESONANCE, GENERAL

first two perturbation terms of the quadrupole interaction. These are the first-order quadrupole interaction (Equation 6),

\[ H_{Q}^{(1)} = N_Q \frac{1}{3} \sqrt{6}(3I_z^2 - I(I + 1))V_{2,0} \]  

and the second-order quadrupole interaction (Equations 7 and 8),

\[ H_{Q}^{(2)} = -\frac{N_Q^2}{2\Lambda}(\frac{1}{2}V_{2,-1}V_{2,1}(4I(I + 1) - 8I_z^2 - 1) + \frac{1}{2}V_{2,-2}V_{2,2}[2I(I + 1) - 2I_z^2 - 1])I_z \]  

\[ N_Q = \frac{\text{eq}}{2I(2I - 1)\hbar} \]

The terms \( V_{2,a} \) are the components of the EFG expressed as a spherical tensor of rank 2. The interaction \( H_{Q}^{(1)} \) in Equation (6) is an even function of \( I_z \). However, in Equation (7), \( H_{Q}^{(2)} \) is an odd function of \( I_z \). That is, Equation (7) can be rewritten as Equation (9):

\[ H_{Q}^{(2)} = A_{Q}^{(2)}I_z^2 + B_{Q}^{(2)}I_z \]

The interaction \( H_{Q}^{(1)} \) is independent of \( w_L \), whereas \( H_{Q}^{(2)} \) is inversely proportional to it. This means that the effect of \( H_{Q}^{(2)} \) decreases when the strength of \( B_0 \) increases.

Under static conditions \( H_{Q}^{(1)} \) can be expressed as Equations (10–12):

\[ H_{Q}^{(1)} = \frac{1}{3}w_Q(3I_z^2 - I(I + 1)) \]  

\[ w_Q = \frac{3}{2}\Omega_Q(3\cos^2 \beta - 1 + \eta \sin^2 \beta \cos 2\alpha) \]  

\[ \Omega_Q = eQ\hbar \]

Combining Equations (11) and (12) gives Equation (13):

\[ y = w_Q \frac{8(2I - 1)\hbar}{3e^2qQ} = 3\cos^2 \beta - 1 + \eta \sin^2 \beta \cos 2\alpha \]

which varies between \(-(1 + \eta)\) and 2, and reaches \(-2\) when \(\eta = 1\). The interval \([-2, 2]\) is divided into \(n\) parts. For a given \(\eta\), the values of \(y\) are computed for every combination of \(\alpha = 2\pi r/M\) and \(\cos \beta = r/M(u, r = 0, \ldots, M)\). The \(y\) values falling into the \(n\) intervals are counted. We chose \(n = 41\) and \(M = 300\). This procedure was proposed by Narita and colleagues.\(^{20}\) It allows us to simulate the powder pattern (i.e. the equivalents of the spectrum of a powder sample) \(P(y)\) of a satellite transition. Therefore, comparing the shape and the spreading of the experimental powder pattern with the simulated one provides the asymmetry parameter and the quadrupole coupling constant, respectively.

The spectral line intensity\(^{21}\) and the echo amplitude (which are dealt with in section 3) do not depend on the sign of \(w_Q\) or \(y\). So \(P(y < 0)\) is co-added to \(P(y > 0)\), reducing the numbers of values of \(P(y)\) to \(2(1 + n)\). Other procedures giving the same result but with less computation time are available.\(^{22,23}\)

2.2 Energy Levels and Spectrum

Figure 1 shows the splitting and shift of the energy levels, as well as those of the absorption lines (simply lines in the remainder of this article) in the spectra for a spin \(I = \frac{3}{2}\) system in a single crystal, when considering \(H_{Q}^{(1)}\) and \(H_{Q}^{(2)}\).

Without \(B_0\), the four energy levels of a free spin-\(I\) system are degenerate (state \(a\)). When the spin system is introduced into \(B_0\), the Zeeman interaction splits these energy levels equally (state \(b\)) with \(|I, m| = \frac{1}{2}, \frac{1}{2}, \frac{1}{2}, -\frac{1}{2}\), and \(|\frac{3}{2}, -\frac{3}{2}\), or simply \(|m| = \frac{3}{2}, \frac{1}{2}, -\frac{1}{2}, -\frac{3}{2}\)). The difference between two consecutive energy levels defines \(w_L\), giving a single line in the spectrum, shown as \(b'\).

The first-order quadrupole interaction generates small shifts of the energy levels. As \(H_{Q}^{(1)}\) is an even function of \(I_z\), the energy-level shifts are an even function of the magnetic number \(m\). Therefore two energy levels having the same \(|m|\) are shifted by the same quantity: \(\langle m|H_{Q}^{(1)}|m\rangle = \pm w_Q\) for a spin \(I = \frac{3}{2}\) (state \(c\)), depending on \(|m|\). The transition \((-\frac{1}{2} \leftrightarrow \frac{1}{2})\) is called the central transition; the other two transitions \((-\frac{1}{2} \leftrightarrow -\frac{1}{2})\) and \((\frac{1}{2} \leftrightarrow \frac{3}{2})\) are called the satellite transitions. As the two energy levels of the central transition are shifted by the same quantity, the line in the spectrum, called the central line, remains at \(w_L\). However, the satellite lines are shifted by \(\pm 2w_Q\) from the central line (shown as \(c'\)).
Figure 1 The four energy levels \(|\frac{1}{2}\rangle, |\frac{3}{2}\rangle, |\frac{1}{2}\rangle, \) and \(|\frac{3}{2}\rangle\) for a spin \(I = \frac{1}{2}\) system in a single crystal in (state a) zero Zeeman field \(B_0\), (b) in the presence of \(B_0\), (c) including the first-order quadrupole interaction \(H_Q^{(1)}\), and (d) including the second-order quadrupole interaction \(H_Q^{(2)}\). Their corresponding spectra are represented as arrows in (b), (c), and (d), respectively. The figure provides definitions of the quadrupole coupling \(Q\) and of the Larmor frequency \(\omega_L\). (a) \(m = 0\), (b) in the presence of \(B_0\) \(2\) system in a single crystal in (state a) zero Zeeman field \(B_0\), (c) including the first-order quadrupole interaction \(H_Q^{(1)}\), and (d) including the second-order quadrupole interaction \(H_Q^{(2)}\). Their corresponding spectra are represented as arrows in (b), (c), and (d), respectively. The figure provides definitions of the quadrupole coupling \(Q\) and of the Larmor frequency \(\omega_L\). (a) \(m = 0\), (b) in the presence of \(B_0\) (c) \(m = 0\), (d) \(m = 0\). The effect of \(H_Q^{(2)}\) is to shift the energy levels further (state d). As a result, an additional shift with respect to \(w_L\), called the second-order quadrupole shift, occurs for each absorption line. However, this second-order quadrupole shift of a line is much smaller than the \(\pm 2w_Q\) shift due to \(H_Q^{(1)}\). As \(H_Q^{(2)}\) is an odd function of \(I_L\), the energy-level shifts are an odd function of \(m\). Therefore, two energy levels having the same \(|m|\) are shifted by the same quantity but in the opposite direction. Even the central line is shifted from \(w_L\) (shown as \(d\)). Therefore the observed position of the central line is not \(w_L\). The direction of the line shift depends on the orientation of \(B_0\) in the PAS of the EFG tensor.

To detect the presence of these split energy levels, a time-dependent perturbation has to be applied.\(^{(24)}\) Continuous wave (CW) NMR applies an RF magnetic field \(B_1\) of very weak amplitude \(w_{RF} = \gamma B_1\), whose Hamiltonian is (Equation 14)

\[
H_{\text{pert}} \propto -w_{RF} I_z \cos \omega_c t
\]

where \(w_c\) is the carrier or the spectrometer frequency. The RF field \(B_1\) is applied perpendicularly to \(B_0\). Therefore, the sample is surrounded with a bath of RF photons of energy \(w_{RF}\).\(^{(25)}\) Excitation of the spin system and detection of its response occur simultaneously by using two RF coils. During the excitation of the spin system by \(B_1\), single quantum (SQ) transitions between two consecutive energy levels as well as MQ transitions between two nonconsecutive energy levels occur.\(^{(26)}\) The probability per second that \(H_{\text{pert}}\) induces a transition between two states \(|m\rangle\) and \(|m'\rangle\) is proportional to \(|\langle m'|I_z|m\rangle|^2\), which vanishes unless \(m' = m \pm 1\). The condition \(\Delta m = \pm 1\) is the selection rule for magnetic dipole transitions. Transverse magnetizations, detected by an RF coil, are related to SQ transitions. The expression \(\zeta^2(m \pm 1, m)\) is used to denote this probability (Equation 15):

\[
\zeta^2(m \pm 1, m) = |\langle m + 1|I_z|m \rangle|^2 = |\langle m|I_z|m + 1 \rangle|^2 = I(I + 1) - m(m + 1)
\]

In the linear regime where the response of the spin system is proportional to the excitation, the spectral line intensity (the area of the absorption line) is proportional to \(\zeta^2\). Table 1 gives the values of \(\zeta^2\) as well as those of the relative spectral line intensity

\[
\frac{\zeta^2}{\sum_{m=-I}^{I} \zeta^2}
\]

for various half-integer spins. The effects of MQ transitions are observed in the nonlinear regime by using a stronger \(B_1\), so that the spin system is forced to absorb several RF photons simultaneously.\(^{(9,27)}\)

In contrast, in pulsed NMR the process of these transitions is investigated only after the end of a strong

</table>
RF pulse by detecting a FID. Excitation and detection are performed with the same RF coil. Also, SQ and MQ transitions occur during the RF pulse, as in CW NMR. As an RF coil can only detect an FID generated by SQ transitions, a second RF pulse is required to probe the effects of MQ transitions.

When MQ transitions between $|m\rangle$ and $|m\rangle$ are detected directly as in CW NMR, the absorption line would be located at about $(m - m)\omega_L$, as the energy-level diagram suggests (state d in Figure 1). In fact this is not the case – the transition between two nonconsecutive energy levels is a multiple-photon process, as shown for a spin $I = \frac{3}{2}$. If $H_Q^{(1)}$ is the dominant interaction (state c), a 2Q transition is a two-photon process and the frequency of the photon is $\omega_L \pm \omega_Q$, depending on the transitions $^{(27,28)}$. The 3Q transition is a three-photon process. The photon frequency of the central and 3Q transitions is $\omega_L^{(2)}$. If $H_Q^{(2)}$ is present, their photon frequency is close to $\omega_L$. From a theoretical point of view, to avoid the effects of the Zeeman interaction on the transition frequency $\omega_{w,q}$ between two energy levels $|w\rangle$ and $|q\rangle$, we define $w_{w,q}$ in the rotating frame of the frequency carrier or, in short, the rotating frame. For the moment, we do not deal with the offset term $H_A = -(\omega_L - \omega_N)I_I$. In other words, the Zeeman interaction is not considered in the definition of $w_{w,q}$ (Equation 16):

\[
w_{w,q} = \langle w|(H_Q^{(1)} + H_Q^{(2)})|w\rangle - \langle q|(H_Q^{(1)} + H_Q^{(2)})|q\rangle = w_{w,q}^{(1)} + w_{w,q}^{(2)}
\]

where $w_{w,q}^{(1)}$ and $w_{w,q}^{(2)}$ are, respectively, the first- and second-order quadrupole shifts of the $(w - q)$ quantum absorption line with respect to $\omega_L$.

In the simplest pulsed NMR experiment that uses a single RF pulse (Figure 2a), two durations are involved – the duration of the RF pulse $t_1$ and that of the signal acquisition $t_2$. Furthermore we define the duration of the FID by $T_{FID}$. An FID in the time domain $F(t_1, t_2)$ and its spectrum in the frequency domain $S(t_1, w_2)$ are related by the Fourier transform of Equation (17):

\[
F(t_1, t_2) = \int_{-\infty}^{+\infty} S(t_1, w_2) \exp(-i\tau w_2) \, dw_2
\]

The amplitude of the FID at the end of the RF pulse is given by Equation (18),

\[
F(t_1, t_2 = 0) = \int_{-\infty}^{+\infty} S(t_1, w_2) \, dw_2
\]

That is, the FID amplitude at the end of the RF pulse is related to the spectral line intensity. In the rotating frame (Figure 2b), the effect of an X pulse is the nutation of the magnetization vector $\mathbf{M}$ around $\mathbf{B}_1$ located along the $x$ axis. The projection of $\mathbf{M}$ or the FID is detected along the $y$ axis. However, the FID amplitude, also denoted by $I_y(t_1)$, is related to the density operator $\rho(t_1)$ as Equation (19),

\[
\langle I_y(t_1) \rangle = F(t_1, t_2 = 0) = \text{Tr} \{ \rho(t_1) I_y \}
\]

where Tr means trace. In practice, the FID is recorded with a quadrature detector. The complex spectral line intensity and the density operator are related by Equation (20):

\[
\langle I_y(t_1) \rangle = \langle I_y(t_1) + iI_x(t_1) \rangle = \text{Tr} \{ \rho(t_1) I_y + iI_x \}
\]

Therefore, knowledge of the density operator allows us to predict the complex spectral line intensity and the dynamics of the spin system as usual (see section 3).

2.2.1 Effect of the First-order Quadrupole Interaction on the Spectrum

Two examples are used to illustrate the effects of $H_{Q}^{(1)}$ on the spectrum. The spectrum of $^{27}$Al ($I = \frac{5}{2}$) from a single...
crystal of $\alpha$-Al$_2$O$_3$ consists of five lines (Figure 3a); the central line is in the middle of four satellite lines, which means that the dominant interaction is $H_Q^{(1)}$. Figure 3(b) is the spectrum of two single crystals. As the central lines of the two crystals remain at $w_L$, they co-add, giving an intense line. In contrast, the two sets of four satellite lines are separated due to different orientations of $\mathbf{B}_0$ in the PAS of the EFG tensor for each crystal.

When the sample is a powder, there is a uniform distribution of the orientations of $\mathbf{B}_0$ in each crystallite. If $H_Q^{(1)}$ is the dominant interaction, the contributions of all crystallites co-add, giving a sharp central line and a broad powder pattern of satellite lines. Figure 4 (spectrum a) shows the case of $^{23}$Na ($I = \frac{1}{2}$) in a powder of NaNO$_3$. The powder pattern can be simulated by using the numerical procedure described in section 2.1.

In a MAS experiment, the powder is packed in a rotor whose spinning axis relative to $\mathbf{B}_0$ is at the magic angle $\theta_m = 54^\circ44'$. In the fast condition, that is if the rotor spinning rate is much larger than the line width, $H_Q^{(1)}$ will be canceled during free precession of the spin system. Otherwise rotational echoes appear in the FID and spinning sidebands in the spectrum. Spectrum (c) in Figure 4 presents the $^{23}$Na ($I = \frac{1}{2}$) MAS spectrum in powdered NaNO$_3$. The shape and the spread of these spinning sidebands enable determination of the asymmetry parameter $\eta$ and the quadrupole coupling constant, respectively.

2.2.2 Effect of the Second-order Quadrupole Interaction on the Spectrum

When $H_Q^{(2)}$ becomes important, the central line is also shifted. For a powder, the central line is also broadened but to a lesser extent than the satellite lines, which spread over the megahertz range. As a result the powder pattern of the central line is generally observed, whereas that of the satellite lines is not. The shape of the central-transition powder pattern depends on the asymmetry parameter $\eta$, as shown by the spectra for three $^{139}$La ($I = \frac{1}{2}$) salts in Figure 5(a–c). Under static conditions, the second-order quadrupole shift of the central line with respect to $w_L$ is given by Equations (21–24):

$$w_{\text{static}}^{(2)} = -\frac{1}{6w_L} \frac{3e^2qQ}{2I(2I-1)\hbar} \left\{ I(I+1) - \frac{3}{4} \right\}$$

$$A(\alpha, \eta) = -\frac{3}{8} + \frac{1}{2} \eta \cos 2\alpha$$

$$B(\alpha, \eta) = \frac{3}{8} - \frac{1}{2} \eta^2 - 2\eta \cos 2\alpha + \frac{3}{4} (\eta \cos 2\alpha)^2$$

$$C(\alpha, \eta) = -\frac{1}{8} + \frac{1}{4} \eta^2 - \frac{1}{2} \eta \cos 2\alpha - \frac{1}{8} (\eta \cos 2\alpha)^2$$

Figure 4 Effect of $H_Q^{(1)}$ on the spectrum of spin $I = \frac{1}{2}$ in a powdered sample. $^{23}$Na ($I = \frac{1}{2}$) spectra of NaNO$_3$ recorded by using (a) static and (c) MAS conditions. The central line is cut off at (b) $\frac{1}{16}$ and (c) $\frac{1}{16}$ of its total height. (Reproduced by permission of Academic Press from J. Skibsted, N.C. Nielsen, H. Bildsøe, H.J. Jakobsen, J. Magn. Reson., 95, 88–117 (1991).)
This shift is inversely proportional to \( w_L \) (see Equation 21). The central-transition powder pattern can be simulated by the angular part of Equations (21–24) using the procedure described in section 2.1. The limits are \([-\frac{2}{3}(1 + \eta), \frac{2}{3}(3 + \eta)^2\] which become \([-\frac{4}{3}, \frac{4}{3}]\) when \( \eta = 1 \). Figure 5(d–f) are the simulated spectra.

Figure 6 shows the powder patterns of \(^{59}\)Co \((I = \frac{7}{2})\) in Na\(_3\)Co(NO\(_2\))\(_6\) whose line width decreases when the strength of \( B_0 \) increases.\(^{33}\) However, above 11 T the dominant interaction becomes the chemical shift anisotropy whose contribution increases with the strength of \( B_0 \).

When the rotor spinning axis is at the angle \( \theta_r (\neq \theta_m) \) relative to \( B_0 \), the experiment is called variable-angle spinning (VAS).\(^{34}\) In the fast condition, the second-order quadrupole shift of the central line with respect to \( w_L \) is defined by Equations (25–28).\(^{18}\)

\[
\frac{w_{-1/2,1/2}^{\text{fast VAS}}}{w_L} = \frac{\Omega_0^2}{w_L} \{ I(I + 1) - \frac{3}{4} \} \times \left( \frac{1}{2} B_{0,0}(\eta) + 4 B_{2,0}(\eta) d_{2,0}^{(3)}(\beta_1) + 2 B_{2,2}(\eta) \right)
\]

\[
\times d_{2,0}^{(4)}(\beta_1) \cos 2\alpha_1 P_2(\cos \theta_1) + 9 B_{4,0}(\eta)
\]

\[
\times e_{0,0}^{(4)}(\beta_1) + 2 B_{4,2}(\eta) e_{0,2}^{(3)}(\beta_1) \cos 2\alpha_1
\]

\[
+ 2 B_{4,4}(\eta) d_{0,4}^{(3)}(\beta_1) \cos 4\alpha_1 P_4(\cos \theta_1)
\]

\[\Omega_0^2 = \left( I(I + 1) - \frac{3}{4} \right) \]

\[B_{0,0}(\eta) = - \frac{3}{4} \left( \frac{3}{2} \eta^2 + 1 \right), \quad B_{2,0}(\eta) = \frac{3}{16} \left( \frac{3}{2} \eta^2 - 1 \right)\]

\[B_{2,\pm 2}(\eta) = \frac{3}{14\sqrt{10}} \eta, \quad B_{4,0}(\eta) = \frac{9}{26} \left( \frac{3}{2} \eta^2 + 1 \right)\]

\[B_{4,\pm 4}(\eta) = \frac{1}{14\sqrt{10}} \eta^2\]

where \( P_2(\cos \theta_1) \) and \( P_4(\cos \theta_1) \) are Legendre polynomials (Equations 29 and 30):

\[P_2(\cos \theta_1) = \frac{1}{2} (3 \cos^2 \theta_1 - 1)\]

\[P_4(\cos \theta_1) = \frac{1}{8} (35 \cos^4 \theta_1 - 30 \cos^2 \theta_1 + 3)\]

The Euler angles \( \alpha_1 \) and \( \beta_1 \) are those of the rotor in the PAS of the EFG tensor. In Equation (25), we can replace \( \Omega_0^2/w_L \) by Equation (31).

\[
\frac{\Omega_0^2}{w_L} = \frac{1}{6w_L} \frac{3e^2 qQ}{2I(2I - 1)\hbar} \cdot \frac{2}{3} \quad (31)
\]
The VAS central-transition powder pattern can be simulated by using Equations (25–31) and the procedure described in section 2.1 with the same limits as in static experiment, that is, \( \left[ -\frac{1}{4}, \frac{3}{4} \right] \). The VAS central-transition powder pattern for \( \theta = 0 \) is identical to the static spectrum.

For MAS experiments in the fast condition, we only need to specify \( \theta = \theta_m \), that is, \( P^2(\cos \theta) = 0 \) in Equation (25) to obtain the expression of the second-order quadrupole shift of the central line with respect to \( w_L \), which is equivalent to the classical relationship (Equations 32–35).

\[
\frac{w^{(2)\text{fast MAS}}_{L-1/2,1/2}}{w_L} = -\frac{1}{6w_L} \frac{3e^2qQ}{2I(2I-1)\eta} \{I(I+1) - \frac{3}{4}\} \\
\times \{D(\alpha_1, \eta)\cos^4 \beta_1 + E(\alpha_1, \eta)\cos^2 \beta_1 \}
\]
\[
+ F(\alpha_1, \eta) \}
\]
\[
D(\alpha_1, \eta) = \frac{21}{\eta^2} - \frac{7}{8} \eta \cos 2\alpha_1 + \frac{7}{2 \eta} \eta \cos 2\alpha_1 \]
\[
E(\alpha_1, \eta) = \frac{9}{8} + \frac{1}{12} \eta^2 + \eta \cos 2\alpha_1 - \frac{7}{2 \eta} \eta \cos 2\alpha_1 \]
\[
F(\alpha_1, \eta) = \frac{5}{\eta} - \frac{1}{8} \eta \cos 2\alpha_1 + \frac{7}{4 \eta} \cos 2\alpha_1 \]

In rapid conditions, the MAS central-transition powder pattern can be simulated by using the angular part of Equations (32–35), and the procedure described in section 2.1 with the limits \( \left[ -\frac{1}{4}(1-\eta)^2, -\frac{1}{4}(1+\eta)^2 \right] \). In practice, the same limits are used as in static conditions in order to compare the line widths. The central-transition powder pattern is narrowed by a factor ranging from three to four with respect to that obtained in static condition, depending on the value of \( \eta \).

For all experiments (static or rotating sample), the second-order quadrupole shift of the center of gravity of the central-transition powder pattern due to \( H_Q^{(2)} \) (Equation 36) is

\[
\frac{w_{L-1/2,1/2}^{(2)\text{iso}}}{w_L} = -\frac{3Q^2I}{10w_L} \{I(I+1) - \frac{3}{4}\} \left(1 + \frac{1}{4} \eta^2\right)^2
\]

with respect to \( w_L \). Experimentally, the center of gravity is the position that divides the integrated area of the powder pattern into two equal parts. The observed chemical shift of the center of gravity of the central-transition powder pattern \( \delta^{(ob)}_{G2} \) comes from two contributions, namely the isotropic chemical shift \( \delta^{(iso)}_{CS} \) and \( w_{L-1/2,1/2}^{(2)\text{iso}} \) such that (Equation 37)

\[
\delta^{(ob)}_{G2} = \delta^{(iso)}_{CS} + \frac{1}{w_L} w_{L-1/2,1/2}^{(2)\text{iso}}
\]

As \( w_{L-1/2,1/2}^{(2)\text{iso}} \leq 0 \), the result \( \delta^{(iso)}_{CS} \geq \delta^{(ob)}_{G2} \) is always true.

Figure 7 shows the MAS spectra of four- and six-coordinated \( ^{27}\text{Al} \) in \( Y_2\text{Al}_3\text{O}_{12} \). The center of gravity of the six-coordinated Al powder pattern, whose spectrum is typical of \( H_Q^{(1)} \), remains at its isotropic chemical shift position whatever the strength of \( B_0 \). In contrast, that of the four-coordinated Al powder pattern shifts towards its isotropic chemical shift when the strength of \( B_0 \) increases because the dominant interaction is \( H_Q^{(1)} \).

![Figure 7](image-url)
remain time independent. Only MAS experiments. As a result, the internal interactions during excitation of the spin system by the RF pulses in the rotor containing the sample appears to be static amplitude because this interaction can be much stronger than the $H_Q$ two-pulse sequences (Figures 2 and 9).

The assumptions during the RF pulses are the same for both static and MAS conditions, and both one- and two-pulse sequences (Figures 2 and 9).

During free precession of the spin system, that is in the absence of RF pulses, interactions neglected during the RF pulses cannot be ignored. The simplification depends on the sample, the nuclei, and the experimental conditions (static or MAS conditions, and the strength of $B_0$). The second-order quadrupole interaction can be neglected with strong $B_0$ or with light nuclei. In MAS experiments, the chemical shift anisotropy, $H_Q^{(2)}$, as well as $H_{D^{(2)IS}}$, are canceled under rapid conditions, whereas $H_{D^{(2)IS}}$ is dramatically reduced.

Throughout this article Hamiltonians $H$, the carrier frequency $\nu_c$, the Larmor frequency $\nu_L$, the RF pulse amplitude $w_{RF}$, and the line positions have been defined in angular frequency units. Only the frequency offsets are expressed in frequency units. Disregarding relaxation phenomena, the dynamics of a spin-$I$ system submitted to two-pulse sequences is described by the density operator $\rho(t_1, t_2, t_3, t_4)$ expressed in the rotating frame. The duration $t_1$ is that of the first RF pulse, $t_2$ is the pulse separation or experimental evolution period, $t_3$ is the second-pulse duration, and $t_4$ the acquisition period (Figure 9). The Hamiltonian of an $X$ pulse is given by Equation (39):

$$H_{RF} = -w_{RF}I_x$$  \hspace{1cm} (39)

### 3 TIME-DOMAIN RESPONSE

In limiting the discussion topics to the effects of interactions on the spectrum, the internal interactions $H_{int}$ are restricted to secular Hamiltonians, that is, to those that commute with the Zeeman interaction. An example is the isotropic chemical shift shown in Equation (38):

$$H_{CS} = -w_c^\delta_{CS}I_z$$ \hspace{1cm} (38)

As the pulse duration is short (some microseconds), the rotor containing the sample appears to be static during excitation of the spin system by the RF pulses in MAS experiments. As a result, the internal interactions remain time independent. Only $H_Q^{(1)}$ is considered because this interaction can be much stronger than the amplitude $w_{RF}$ of the RF pulse; thus the offset or shift interactions and $H_Q^{(2)}$ can be neglected. Homonuclear $H_{D^{(2)I}}$ and heteronuclear $H_{D^{(2)IS}}$ magnetic dipole–dipole interactions are also neglected during strong RF pulses. The assumptions during the RF pulses are the same for both static and MAS conditions, and both one- and two-pulse sequences (Figures 2 and 9).
The spin dynamics from the Boltzmann equilibrium to the acquisition period are followed by using the density operators. In the high-temperature approximation, the initial state is described by the Boltzmann density operator $\rho(0) = I_z$. At the end of the first RF pulse the density operator is defined by Equation (40):

$$\rho(t_1) = \exp[-i(H_{int} + H_{RF})t_1]\rho(0)\exp[i(H_{int} + H_{RF})t_1]$$  \hspace{1cm} (40)

Although the matrix representation of the secular Hamiltonian $H_{int}$, expressed in the eigenstates $|m\rangle$ of the Zeeman interaction $H_z$, is diagonal, this is not the case for $H_{RF}$. The matrix representation of $\exp[-i(H_{int} + H_{RF})t_1]$ is the matrix whose elements are the exponential of each matrix element of $(H_{int} + H_{RF})$ if the latter is diagonal. Therefore, the first step is to diagonalize the matrix of $(H_{int} + H_{RF})$. For simplicity the matrix is denoted by the same symbol as the Hamiltonian. The eigenvalue matrix $\Omega$, the eigenvector matrix $T$, and $(H_{int} + H_{RF})$ are related (Equation 41) as

$$\Omega = T(H_{int} + H_{RF})T^\dagger$$  \hspace{1cm} (41)

where $T^\dagger$ is the complex conjugate of the transposed matrix of $T$. The calculation of $\Omega$ and $T$ has been done analytically (Equation 42) for

$$H = H_{Q}^{(1)} + H_{RF}$$  \hspace{1cm} (42)

in three cases: $I = \frac{1}{2}$, \(\frac{3}{2}\), \(\frac{5}{2}\), \(\frac{7}{2}\). Otherwise we can always use a numerical procedure. The density matrix of Equation (40) becomes (Equation 43)

$$\rho(t_1) = T \exp(-i\Omega t_1)T^\dagger \rho(0)T \exp(i\Omega t_1)T^\dagger$$  \hspace{1cm} (43)

After the first RF pulse, the density matrix is given by Equation (44),

$$\rho(t_1, t_2) = \exp(-iH_{int}t_2)\rho(t_1)\exp(iH_{int}t_2)$$  \hspace{1cm} (44)

The effect of the second RF pulse is described by Equation (45),

$$\rho(t_1, t_2, t_3) = T \exp(-i\Omega t_3)T^\dagger \rho(t_1, t_2)T \exp(i\Omega t_3)T^\dagger$$  \hspace{1cm} (45)

Finally, the density matrix during the acquisition period in a two-pulse sequence is

$$\rho(t_1, t_2, t_3, t_4) = \exp(-iH_{int}t_4)\rho(t_1, t_2, t_3)\exp(iH_{int}t_4)$$  \hspace{1cm} (46)

Calculation of $\rho(t_1, t_2, t_3, t_4)$ requires 16 matrix multiplications. It would take a lot of time to perform them analytically to find out the position of the echo and the expression of the spin echo amplitude. Fortunately, careful analysis of $\rho(t_1, t_2, t_3, t_4)$ shows that only 12 matrix multiplications are needed (see sections 3.4.3 and 3.5.5).

### 3.1 One-pulse Sequence: Two-dimensional Nutation Experiment

In a one-pulse experiment, the Hamiltonian during the RF pulse is Equation (42), and that of the acquisition period is $H_{int} = H_{Q}^{(1)}$. First we describe the density matrix $\rho(t_1)$ at the end of the RF pulse. Then we discuss the simplest 2-D method, called nutation.

#### 3.1.1 Spin Operators for $I > \frac{1}{2}$

A matrix element of a spin operator $O$ is denoted by $\langle r|O|c\rangle$ where the magnetic numbers $r$ and $c$ are half-integer numbers associated with the row and column of $\langle r|O|c\rangle$ in the matrix. We use the spin $I = \frac{1}{2}$ to describe the physical meanings of the density matrix elements at the end of the RF pulse. The extension to other spins is easy. A generalization of the three spin operators $I_x$, $I_y$, and $I_z$ used to describe the dynamics of spin $I = \frac{1}{2}$ system are introduced for spins $I > \frac{1}{2}$: $I_x^{w,q}$, $I_y^{w,q}$, and $I_z^{w,q}$. Their matrix representations in the eigenstates of $I_z$ are given by Equation (47).
These \((2I + 1) \times (2I + 1)\) matrices have only two nonzero elements. From Equation (47) we deduce that if we permute the two magnetic numbers \(w\) and \(q\), we obtain Equation (48):

\[
I^w_q = I^q_w, \quad I^w_q' = -I^q_w', \quad I^w_q'' = -I^q_w''
\]

(48)

The operators \(I_x, I_y,\) and \(I_z\) are related to those of Equation (47) as Equations (49–52):

\[
I_x = \sum_{w,q} \sqrt{C(w, q)} I^w_q
\]

(49)

\[
I_y = \sum_{w,q} \sqrt{C(w, q)} I^w_q'
\]

(50)

\[
I_z = \sum_{w,q} C(w, q) I^w_q''
\]

(51)

\[
C(w, q) = I(I + 1) - wq
\]

(52)

In particular \(C(m, m + 1) = \xi^2\), with \(\xi\) being defined by Equation (15). The operator \(I_x\) is related to the \(X\)-pulse (Equation 39) and the operator \(I_z\) is related to the time-domain signal (Equations 19 and 20; Figure 2). For example, \(I = \frac{1}{2}\) gives Equations (53–55):

\[
I_x = \sqrt{5} I^x_y + \sqrt{8} I^x_z + 3 I^x_x + \sqrt{8} I^x_z + \sqrt{8} I^x_x + \sqrt{8} I^x_z + \sqrt{8} I^x_x
\]

(53)

\[
I_y = \sqrt{5} I^y_x + \sqrt{8} I^y_z + 3 I^y_y + \sqrt{8} I^y_z + \sqrt{8} I^y_x + \sqrt{8} I^y_z + \sqrt{8} I^y_x
\]

(54)

\[
I_z = 5 I^z_x + 8 I^z_y + 9 I^z_z + 8 I^z_x + 9 I^z_z + 8 I^z_x + 9 I^z_z + 8 I^z_x
\]

(55)

The matrix forms are given by Equations (56–58):

\[
I_x = \frac{1}{2} \begin{pmatrix}
\frac{5}{2} & \frac{3}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{3}{2} & -\frac{5}{2} \\
\frac{3}{2} & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{3}{2} & -\frac{5}{2} \\
\frac{1}{2} & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{3}{2} & -\frac{5}{2} \\
0 & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{3}{2} & -\frac{5}{2} \\
0 & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{3}{2} & -\frac{5}{2} \\
0 & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{3}{2} & -\frac{5}{2} \\
\end{pmatrix}
\]

(56)

The two matrices of Equations (56) and (57) can also be obtained from Equation (59):

\[
I_x = \frac{1}{2} (I_+ + I_-); \quad I_y = \frac{1}{2i} (I_+ - I_-)
\]

(59)

where \(I_+\) and \(I_-\) are the raising and the lowering operators.

3.1.2 Meanings of the Matrix Elements of \(\rho(t_1)\)

A density matrix element \(\langle w | \rho(t_1) | w \rangle\) in the main diagonal of \(\rho(t_1)\) is defined by

\[
\langle w | \rho(t_1) | w \rangle = \text{Tr}[\rho(t_1) I^w_q]
\]

(60)

In other words, the main diagonal matrix element \(\langle w | \rho(t_1) | w \rangle\) is the spin population of the energy level \(|w\rangle\). The density matrix element \(\langle a | \rho(t_1) | b \rangle\) below the main diagonal is defined by Equation (61):

\[
\langle a | \rho(t_1) | b \rangle = \text{Tr}[\rho(t_1) I^{a,b}_y] + i \text{Tr}[\rho(t_1) I^{a,b}_y]
\]

(61)

with the magnetic numbers \(a\) and \(b\) satisfying the condition \(a < b\). The density matrix element \(\langle w | \rho(t_1) | q \rangle\) above the main diagonal is defined by Equation (62):

\[
\langle w | \rho(t_1) | q \rangle = \text{Tr}[\rho(t_1) I^{w,q}_x] - i \text{Tr}[\rho(t_1) I^{w,q}_x]
\]

(62)
with $w > q$. The density matrix elements $(I^{w, p}_{r}(t_1))$ and $(I^{w, 0}_{r}(t_1))$ are the spectral intensities of off-resonance lines because they are complex quantities. More generally, the density matrix element $(r|\rho(t_1)|c)$ is called the $p$-quantum (pQ) coherence where $p = r - c$ is the coherence order. The spin populations of the energy levels are zero-quantum coherences. The matrix element $(w|\rho(t_1)|-w)$ in the second main diagonal (Equation 63),

$$
(w|\rho(t_1)|-w) \equiv -i(I^{w, -w}_{w}(t_1)) = -i\text{Tr}[\rho(t_1)I^{w, -w}_{w}]
$$

is an imaginary quantity. As the dispersion spectral line intensity $(I^{w, -w}_{w}(t_1)) = 0$, $(w|\rho(t_1)|-w)$ is related to the spectral intensity of the off-resonance absorption line. The SQ or ±1Q coherences induce an RF voltage in the RF coil. These oscillating voltages are observed as an FID that follows the RF pulse. In contrast, MQ coherences do not induce an RF voltage. As a result, no signal is detected.

Figure 10 gives the density matrix $\rho(t_1)$ at the end of an $X$ pulse for a spin $I = \frac{5}{2}$. The first-diagonal elements above the main diagonal of the density matrix are called 1Q coherences, the second-diagonal elements above the main diagonal are called 2Q coherences, and so on. The coherences below the main diagonal elements have a negative value of $p$. The RF coil only detects ±1Q coherences. As the pQ coherences are the complex conjugates of the $-pQ$ coherences, we consider only the $-1Q$ coherences during the acquisition period.

The RF pulse dephased by an angle $\varphi_1$ relative to an $X$ pulse is an important ingredient of MQ/MAS methodology$(47)$ (section 3.5.8). A density matrix element of a $\varphi_1$ pulse is related to that of an $X$ pulse by

$$
\begin{array}{ccccccc}
|\frac{5}{2}\rangle & |\frac{3}{2}\rangle & |\frac{1}{2}\rangle & |\frac{1}{2}\rangle & |\frac{3}{2}\rangle & |\frac{5}{2}\rangle \\
\langle \frac{5}{2}| & \langle \frac{5}{2} - \frac{5}{2}| & \langle \frac{5}{2} - \frac{3}{2}| & \langle \frac{5}{2} - \frac{1}{2}| & \langle \frac{5}{2} - \frac{3}{2}| & \langle \frac{5}{2} - \frac{5}{2}| \\
\langle \frac{3}{2}| & \langle \frac{3}{2} - \frac{5}{2}| & \langle \frac{3}{2} - \frac{3}{2}| & \langle \frac{3}{2} - \frac{1}{2}| & \langle \frac{3}{2} - \frac{3}{2}| & \langle \frac{3}{2} - \frac{5}{2}| \\
\langle \frac{1}{2}| & \langle \frac{1}{2} - \frac{5}{2}| & \langle \frac{1}{2} - \frac{3}{2}| & \langle \frac{1}{2} - \frac{1}{2}| & \langle \frac{1}{2} - \frac{3}{2}| & \langle \frac{1}{2} - \frac{5}{2}| \\
\langle -\frac{1}{2}| & \langle -\frac{1}{2} - \frac{5}{2}| & \langle -\frac{1}{2} - \frac{3}{2}| & \langle -\frac{1}{2} - \frac{1}{2}| & \langle -\frac{1}{2} - \frac{3}{2}| & \langle -\frac{1}{2} - \frac{5}{2}| \\
\langle -\frac{3}{2}| & \langle -\frac{3}{2} - \frac{5}{2}| & \langle -\frac{3}{2} - \frac{3}{2}| & \langle -\frac{3}{2} - \frac{1}{2}| & \langle -\frac{3}{2} - \frac{3}{2}| & \langle -\frac{3}{2} - \frac{5}{2}| \\
\langle -\frac{5}{2}| & \langle -\frac{5}{2} - \frac{5}{2}| & \langle -\frac{5}{2} - \frac{3}{2}| & \langle -\frac{5}{2} - \frac{1}{2}| & \langle -\frac{5}{2} - \frac{3}{2}| & \langle -\frac{5}{2} - \frac{5}{2}| \\
\end{array}
$$

0Q 1Q 2Q 3Q 4Q 5Q

Figure 10 Definition of pQ coherences with the spin $I = \frac{5}{2}$ density matrix at the end of an $X$ pulse, the coherence order $p$ being an integer ranging from $-5$ to $5$. The main diagonal contains real values, whereas the second main diagonal contains pure imaginary values. The other matrix elements are complex values. This matrix is a hermitian one. Matrix elements in the same parallel to the main diagonal have the same coherence order.
Equation (64): \[ \langle r|\rho_1(t_1)|c \rangle = \langle r|\rho(t_1)|c \rangle \exp[-i(r - c)\psi_1] = \langle r|\rho(t_1)|c \rangle \exp(-ip\psi_1) \] (64)

In other words, when an RF pulse is dephased by an angle \( \psi_1 \), a \( pQ \) coherence is dephased by \( \exp(-ip\psi_1) \), whereas the zero-quantum coherences or spin populations are not affected.\(^{(8,25)}\)

### 3.1.3 Spectral Line Intensity and Excitation Condition

The RF pulse amplitude \( w_{RF} \) is usually higher than internal interactions, except the quadrupole interaction. Therefore at least \( H_Q^{(1)} \) must be taken into account during the RF pulse to predict the spin dynamics. Two extreme cases appear:

1. When \( w_Q \ll w_{RF} \), all the transitions are irradiated uniformly, and the excitation is known as nonselective or hard-pulse excitation because \( H_Q^{(1)} \) need not be considered during the RF pulse.
2. When \( w_Q \gg w_{RF} \), two consecutive energy levels are generally irradiated, and the excitation is said to be selective because the multilevel system is reduced to a two-energy-level system whose absorption line is on resonance and \( H_Q^{(1)} \) is taken into account during the RF pulse.

For nonselective excitation, the relative spectral line intensity \( I_{NS}^{m+1,m} \) of the transition \((m+1 \leftrightarrow m)\) is (Equation 65)\(^{(50,51)}\)

\[ I_{NS}^{m+1,m} = \frac{\zeta^2}{I-1} \sum_{m=-I}^{I-1} \zeta^2 \sin w_{RF}t_1 \] (65)

For selective excitation, the relative spectral line intensity \( I_S^{m+1,m} \) of the transition \((m+1 \leftrightarrow m)\) is (Equation 66)\(^{(50,51)}\)

\[ I_S^{m+1,m} = \frac{\zeta}{I-1} \sum_{m=-I}^{I-1} \zeta^2 \sin \zeta w_{RF}t_1 \] (66)

Comparison of Equations (65) and (66) shows that for selective excitation the pulse duration that maximizes the relative spectral line intensity of the on-resonance transition \((m+1 \leftrightarrow m)\) is \( \zeta \) times as short as that for the nonselective excitation. Furthermore, there is also a loss of relative spectral line intensity by the same factor \( \zeta \).\(^{(52)}\) If the pulse duration is sufficiently short, Equation (67),

\[ \sin \zeta w_{RF}t_1 \approx \zeta w_{RF}t_1 \] (67)

then Equations (65) and (66) become identical:

\[ I_{NS}^{m+1,m} \approx I_S^{m+1,m} \approx \frac{\zeta^2}{I-1} w_{RF}t_1 \sum_{m=-I}^{I-1} \zeta^2 \] (68)

Although Equation (68) has been deduced from two relationships with limited validity, it becomes valid for both \( w_Q \ll w_{RF} \) and \( w_Q \gg w_{RF} \) provided that the pulse duration is sufficiently short. Consequently, by continuity, Equation (68) remains valid for any ratio of \( w_Q/w_{RF} \). In other words, there is a linear region in which the relative spectral line intensity is independent of \( w_Q \), if the transition is excited on resonance with a short pulse duration.

Analytical expressions of the spectral line intensity for spins \( I = \frac{1}{2} \) are available for any \( w_Q/w_{RF} \) ratio. Taking an internal interaction such as \( H_Q^{(1)} \) during the RF pulse is called soft-pulse excitation, which includes both nonselective and selective excitations. For spin \( I = \frac{5}{2} \), a numerical procedure must be applied to solve Equations (41) and (43). The SQ spectral line intensity is not given by \( \langle I_{NS}^{m+1,w}(t_1) \rangle = \text{Tr}[\rho(t_1)I_y^{m+1,w}] \), as shown in Figure 11 for a spin \( I = \frac{5}{2} \), but by Equation (69):

\[ \langle I_{NS}^{m+1,w}(t_1) \rangle \approx \zeta(w + 1, w) \text{Tr}[\rho(t_1)I_y^{m+1,w}] \] (69)

This is because SQ coherences are detected directly by an RF coil, in contrast to MQ coherences. As the quadrupole coupling \( w_Q \) depends on the orientations of \( B_i \) with respect to the crystal, a computer is needed to average the response of the spin system over all of these orientations in order to predict the experimental FID amplitude for a powder sample.\(^{(57)}\)

As the NMR absorption line is proportional to the number of spins, the usual way to quantify the number of spins is to compare it with a sample containing a known quantity of spins. Unfortunately, a delay of a few microseconds is necessary before acquisition of the FID. This delay, which depends on the design of the probe head, is called the dead-time of the receiver (Figure 2a). If the latter is much shorter than \( T_{FID} \), the loss of spectral line intensity is negligible and the quantification of the number of spins is reliable. This is the case in high-resolution liquid-state NMR. In solid-state NMR, the absorption lines are broad, that is, \( T_{FID} \) is short. The dead-time of the receiver becomes a significant part of

---

the FID and the quantification of the number of spins may not be reliable.

3.1.4 One-dimensional and Two-dimensional Nutation Experiments

The spectral line intensity is a sum of \((I + \frac{1}{2})^2\) sine functions\(^\text{(58)}\) whose angular frequencies are the nutation frequencies of the spin system around the RF field \(B_1\). Study of the spectral line intensity versus the pulse duration leads to the first 2-D NMR experiment for half-integer quadrupole spins, and is called the 1-D nutation experiment. Fourier transform of the spectral line intensity with respect to the pulse duration is called the 2-D NMR experiment. Fourier transform of the spectral line intensity versus the pulse duration. The spectral line intensity is a sum of functions \(B\) frequencies of the spin system around the RF field \(\omega_{RF}\). The values of \(\varepsilon\) (see Table 1) have not been considered here.

3.1.4.1 Spin \(I = \frac{1}{2}\) Figure 13 shows the \(^{23}\text{Na} (I = \frac{1}{2})\) stacked plotted MAS spectra of a mixture of powdered NaCl and NaNO\(_2\) for increasing pulse duration.\(^\text{(60)}\)

The powder pattern of Na in NaNO\(_2\) is typical of a central line affected by \(H_0\), in agreement with the noncubic crystallographic structure of NaNO\(_2\). However, the powder pattern of Na in NaCl has a featureless line shape. As NaCl has a cubic crystallographic structure, the EFG around the sodium site must be very small, if any. All the three absorption lines (one central and two satellite lines) are not resolved in NaCl. It is well known that the NMR spectral line intensities are related to the number of spins in the sample; the ratio of two lines should give the spin population ratio. Figure 13 clearly shows that the spectral line intensity ratio varies with the pulse duration, giving any spin population ratio. This odd behavior is in agreement with the analytical result of Figure 14(a), showing the central-line intensity of a spin \(I = \frac{1}{2}\) system versus the pulse duration for several \(w_Q/w_{RF}\) ratios.\(^\text{(59)}\)

Only when the pulse duration is sufficiently short is the central-line intensity independent of the \(w_Q/w_{RF}\) ratio. However, for satellite transitions (Figure 14b),\(^\text{(60)}\) there is no linear region where the satellite-line intensity is independent of the \(w_Q/w_{RF}\) ratio. This is because the
whereas the $^{23}$Na experimental spectral line intensity ratio does not depend on $w$

Figure 15, ratio is that of the spin populations. For example in must be taken to ensure that the spectral line intensity satellite lines become increasingly off resonance when $w$

Figure 16 shows the $^{23}$Na 2-D nutation MAS spectrum of powdered NaCl (line at 0 kHz) and NaNO$_2$ (line at $-1.5$ kHz) versus the pulse duration $t_1$, with a recycle delay $D_0 = 60$ s.

full spectrum (see Table 1), multiplying the experimental spectral line intensity ratio by 10/4 indeed gives the spin population ratio.

The main problem in quantifying the spin population is not only the application of a short pulse duration but also the identification of the nature of a featureless line shape (a central line or the full spectrum). One way to proceed with this is to study its behavior with respect to the pulse duration and compare it with the simulation. If the quadrupole coupling constant is relatively small, all the spectral line intensities should be detected.

Figure 16 shows the $^{23}$Na 2-D nutation MAS spectrum of the same mixture of NaCl and NaNO$_2$. Peak B is the 2-D line of NaNO$_2$, whereas peaks A and A’ are those of NaCl. The latter two peaks are located at $w_{RF}$ and $2w_{RF}$, respectively, along the nutation axis. Peak B is located at $2w_{RF}$ because $\zeta = 2$ for $I = \frac{5}{2}$ (Table 1). The positions of peaks A and B are in agreement with the strength of the EFG around the sodium nuclei in the two compounds. The EFG around sodium nuclei in NaCl is nearly zero; the nutation frequency is that of a free spin not submitted to the quadrupole interaction. The nutation frequency of sodium nuclei in NaNO$_2$ is $2w_{RF}$ because the quadrupole coupling constant and therefore the quadrupole coupling is much larger than $w_{RF}$. Peak A’ occurs because the recycle delay $D_0$ in this experiment is too short compared to the spin–lattice relaxation time $T_1$ of sodium nuclei. A fuller explanation is given in section 3.1.4.3. The $^{23}$Na 2-D nutation experiment has been applied to zeolite NaA.$^{(62)}$

3.1.4.2 Spin $I = \frac{5}{2}$ The spin $I = \frac{5}{2}$ is not developed here because numerous papers deal with aluminum nuclei $^{27}$Al ($I = \frac{5}{2}$) in zeolites.$^{(50,63–66)}$ The effects of pulse duration on the central-line shape are shown in

satellite lines become increasingly off resonance when the $w_Q/w_{RF}$ ratio increases. The effective RF field that the spin system is submitted to differs with $B_1$.

For a short pulse duration the spectral line intensity ratio does not depend on $w_Q$. However, precautions must be taken to ensure that the spectral line intensity ratio is that of the spin populations. For example in Figure 15,$^{(59,60)}$ the molar ratio of NaNO$_2$ to NaCl is 6.50, whereas the $^{23}$Na experimental spectral line intensity ratio is 2.50. These two ratios are very different. As the central line of the spin $I = \frac{5}{2}$ system represents 4/10 of the

Figure 12 Nutation experiment. (a) The two time-domain parameters involved in 2-D experiments – the pulse duration $t_1$ describes the evolution period whereas $t_2$ describes the acquisition period. (b) $F(t_1, t_2)$ is a series of FID acquired with increasing pulse duration $t_1$. (c) $F(t_1, w_2)$, the Fourier transform of $F(t_1, t_2)$ with respect to $t_2$, is a series of spectra with increasing pulse duration $t_1$. (d) $F(w_1, w_2)$, the Fourier transform of $F(t_1, w_2)$ with respect to $t_1$, is the 2-D nutation spectrum. $F_1$ is the usual chemical shift axis and $F_1$ is the nutation frequency axis. The peak is located at $w_{RF}$ in the $F_1$ dimension and $w_1$ in the $F_2$ dimension for a spin $I = \frac{5}{2}$ system.
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 14 Calculated one-pulse spectral line intensities for a spin $I = \frac{3}{2}$ in a single crystal and submitted to $H_{RF}^1$ during the RF pulse versus the pulse duration $t_1$ for several values of the quadrupole coupling $w_Q (w_Q/2\pi = 0, 30, 50, \text{and} 500 \text{kHz})$, with $w_{RF}/2\pi = 50 \text{kHz}$: (a) the central transition ($-\frac{1}{2} \leftrightarrow \frac{1}{2}$); (b) the two satellite transitions ($\frac{1}{2} \leftrightarrow \frac{3}{2}$) and ($\frac{3}{2} \leftrightarrow \frac{1}{2}$).

Figure 15 Quantification of spin populations with a short pulse duration $t_1 = 0.25 \mu\text{s}$: one-pulse $^{23}\text{Na} (I = \frac{3}{2})$ MAS spectrum and the integrated area in a mixture of powdered NaCl (line at 0 kHz) and NaN$_2$ (line at $-1.5 \text{kHz}$) with $D_0 = 60 \text{s}$. The molar ratio NaN$_2$/NaCl is 6.50.

Figure 16 $^{23}\text{Na} (I = \frac{3}{2})$ 2-D nutation MAS spectrum (magnitude mode) in a mixture of powdered NaCl (peaks A and A$'$) and NaN$_2$ (peak B) with $D_0 = 5 \text{s}$.

Figure 17 which is the MAS central line of $^{55}\text{Mn} (I = \frac{5}{2})$ in KMnO$_4$. Only short pulse durations ($<3 \mu\text{s}$) yield undistorted MAS powder patterns in agreement with frequency-domain results.

3.1.4.3 Spin $I = \frac{3}{2}$ The FID amplitude in the steady state $\langle I_y(t_1) \rangle$ is related to that in the Boltzmann state $\langle I_y(t_1) \rangle$, the recycle delay $D_0$, and the spin–lattice relaxation time $T_1$ (Equation 70)\cite{8,67}:

$$\langle I_y(t_1) \rangle = \langle I_y(t_1 = 0) \rangle \left[ 1 - \exp(-D_0/T_1) \right] \sin w_{RF} t_1$$

where $w_{RF} = w_{RF}^1 = w_{RF}^2$.

Figure 18 represents the graphs of $\langle I_y(t_1) \rangle$ versus the pulse flip angle $w_{RF} t_1$, ranging from 0 to $\pi$, for various ratios of $D_0/T_1$. The maximums of each curve as well as the associated pulse flip angle $w_{RF} t_1$ decrease when the $D_0/T_1$ ratio decreases. Only the duration of the $\pi$ pulse, which yields a zero signal, does not depend on the $D_0/T_1$ ratio. Experimentally, the $\pi$-pulse duration is determined first with an aqueous solution, then the $\pi/2$-pulse duration is deduced by taking half the $\pi$-pulse duration.

Figure 19(a) represents, in magnitude, the Fourier transform of Equation (70) with respect to the pulse duration, for various $D_0/T_1$ ratios. It shows peaks...
at manifolds of $w_{RF}$. The number of peaks increases when the $D_0/T_1$ ratio decreases. We have checked this spin–lattice relaxation effect with cesium nuclei $^{133}$Cs ($I = \frac{7}{2}$) in a powdered CsCl (Figure 19b). By comparing the two graphs of Figure 19, the spin–lattice relaxation time of cesium is estimated to be about 300 s.

3.1.4.4 Spin $I = \frac{9}{2}$ The largest stable nuclear spin for NMR is $I = \frac{9}{2}$. The nucleus most studied is niobium $^{93}$Nb. Figure 20 shows the 2-D nutation spectrum of $^{93}$Nb in a mixture of powdered LiNbO$_3$ and NbO$_2$F.$^{68}$ The crystallographic structure of NbO$_2$F is cubic, whereas that of LiNbO$_3$ is rhombohedral. Peak A corresponds to
3.2 Composite-pulse Sequences: Spurious Signal Suppression

Spurious signals in pulsed NMR are often observed. They disturb the signals in such a way that the interpretation of the spectra becomes difficult. We will focus on two kinds of spurious signals:

1. acoustic ringing from the NMR probe during the study of low gyromagnetic ratio nuclei in strong $B_0$;
2. piezoelectric signals that occur when ferroelectric materials are studied in single crystal form.

This section discusses the first kind of spurious signal, postponing the second case to section 3.5.3. Figure 21(a) shows the $^{131}$Xe ($I = \frac{7}{2}$) one-pulse spectra of xenon gas physisorbed in NaY zeolite, for increasing pulse durations (71). The baselines of these spectra are so distorted that the $^{131}$Xe signals are difficult to recognize. A composite-pulse sequence consisting of three successive RF pulses of the same duration $t_1$ (Figure 22) was applied with the following phases (71):

- first RF pulse: $-X$ $-X$ $+X$ $+X$
- second RF pulse: $+X$ $+X$ $+X$ $+X$
- third RF pulse: $+X$ $-X$ $-X$ $+X$

This sequence, called sequence 1, consists of $X$ and $-X$ pulses. Figure 21(b) presents $^{131}$Xe ($I = \frac{3}{2}$) spectra acquired with the composite-pulse sequence. These spectra have flattened baselines, allowing the $^{131}$Xe signal to be recognized. The signal has a featureless line shape which does not allow the conclusion that the $^{131}$Xe nuclei are submitted to quadrupole interaction. One response to this question is to study the behavior of the spectral line intensity versus the pulse duration $t_1$.

The Hamiltonian during an $X$ pulse (Equation 71) is

$$H^{(X)} = H_Q^{(1)} - w_{RF} I_x$$

(71)

The Hamiltonian during a $-X$ pulse (Equation 72) is

$$H^{(-X)} = H_Q^{(1)} + w_{RF} I_x$$

(72)

The two Hamiltonians $H^{(X)}$ and $H^{(-X)}$ have the same eigenvalue matrix $\Omega$, but different eigenvector matrices, denoted by $T$ and $U$, respectively. The central-line intensity is given by $\xi \left( \frac{1}{2}, -\frac{1}{2} \right) \text{Tr} \left\{ \rho_1(t_1) - \rho_2(t_1) + \rho_3(t_1) - \rho_4(t_1) \right\} l_z \left( \frac{1}{2}, -\frac{1}{2} \right)$, where the signs of the four density operators $\rho_j(t_1)$ are those of the receiver phase given in sequence 1, with (Equation 73)

$$\rho_1(t_1) = T \exp(-2i\Omega t_1) T^\dagger U \exp(-i\Omega t_1) U^\dagger \rho(0) U \times \exp(i\Omega t_1) U^\dagger T \exp(2i\Omega t_1) T^\dagger$$

(73)

for the first acquisition of the FID. For the second FID acquisition Equation (74) applies:

$$\rho_2(t_1) = U \exp(-i\Omega t_1) U^\dagger T \exp(-i\Omega t_1) T^\dagger U \times \exp(-i\Omega t_1) U^\dagger \rho(0) U \exp(i\Omega t_1) U^\dagger T \times \exp(i\Omega t_1) U^\dagger$$

(74)
ties of a spin

For the last acquisition Equation (76) is used:

$$H$$

into account

determine the two quadrupole parameters. However, this

Fitting the experimental spectral line intensity versus the

duration $$t_1$$. As $$w_{RF}$$ has a limited range of variation, to

increase the number of independent experimental parameters we can apply a two-pulse sequence (Figure 9a). Keeping $$w_{RF}$$ at its maximum value provided by the high-power amplifier so that our assumptions remain valid (Figure 9), we have three time-domain parameters: the durations $$t_1$$ and $$t_2$$ of the two RF pulses, and the pulse separation $$\tau_2$$. The graph of the spectral line intensity versus one of these three parameters, the other two being constant, allows us to extract the two quadrupole parameters. Fitting two sets of experimental spectral line intensities, obtained with different values of the two constants, should provide us with the same quadrupole parameters. In practice, we apply both one- and two-pulse sequences. As the delay required to fit the one-pulse spectral line intensities is short, we use the two quadrupole parameters provided by the one-pulse experiment as initial values to fit the two-pulse sequence data.

The internal interaction throughout the two-pulse experiment is $$H_Q^{(1)}$$. The analytical expressions of the central-line intensity after the second RF pulse for spins $$I = \frac{1}{2}$$, $$\frac{3}{2}$$, and $$\frac{7}{2}$$ in a single crystal are available. Fortunately they can be calculated numerically. As the spin–lattice relaxation is not taken into account, the pulse separation $$\tau_2$$ must be short. It is of the order of magnitude of the dead-time of the receiver (typically 10–20 µs). All the density matrix elements at the end of the first RF pulse contribute to the spectral line intensity at the end of the second RF pulse. Equations (43–45) are used to calculate the central-line intensities, which are given by $$\zeta(-\frac{1}{2}, \frac{1}{2})$$ for powder samples the procedure described in section 2.1 should be used to average the quadrupole coupling $$w_Q$$.

Figure 23 presents the $$^{23}\text{Na}$$ ($$I = \frac{3}{2}$$) spectra of NaNO$_3$ acquired with the two-pulse sequence for increasing second-pulse duration.\(^{52}\) The Na central line has featureless line shape, irrelevant for line-shape analysis for the extraction of quadrupole parameters. Figure 25 shows the fitting of the experimental central-line intensities versus the second-pulse duration.\(^{72}\) The result of the fitting for the quadrupole coupling constant is quite good.

Two-pulse sequences without pulse separation, that is, $$\tau_2 = 0$$, such as the spin-lock sequence\(^{48,76}\) or the rotary echo sequence,\(^{77}\) can also be applied to determine the quadrupole parameters from a featureless line shape.

### 3.4 Solomon Echo Sequences

The FIDs that have short durations $$T_{FID}$$ are lost in the dead-time of the receiver following an RF pulse. This is the case of the FIDs of the satellite transitions whose powder pattern spreads far out from the central line. As the satellite-transition powder pattern provides us with the quadrupole parameters, we should apply the

![](images/figure23.png)

**Figure 23** Calculated central-line intensities for spin $$I = \frac{3}{2}$$ in a powder sample, excited by the composite-pulse sequence of Figure 22, versus the pulse duration $$t_1$$ for several values of the quadrupole coupling constant $$e^2 q Q / \hbar$$ (0, 100, 200, and 1000 kHz), with $$\eta = 0$$ and $$w_{RF} / (2\pi) = 50$$ kHz.

Equation (75) is for the third acquisition:

$$\rho_3(t_1) = U \exp(-i\Omega t _1) U^\dagger T \exp(-2i\Omega t _1)T_l^2 \rho(0)T_l^2 \times \exp(2i\Omega t _1)T_l^2 U \exp(i\Omega t _1) U^\dagger$$

For the last acquisition Equation (76) is used:

$$\rho_4(t_1) = T \exp(-3i\Omega t _1)T_l^2 \rho(0)T_l^2 \exp(3i\Omega t _1)T_l^2$$

3.3 Two-pulse Sequences

Fitting the experimental spectral line intensity versus the pulse duration of the one-pulse sequence allows us to determine the two quadrupole parameters. However, this sequence depends only on two independent experimental parameters, the RF pulse amplitude $$w_{RF}$$ and the pulse duration $$t_1$$. As $$w_{RF}$$ has a limited range of variation, to increase the number of independent experimental parameters we can apply a two-pulse sequence (Figure 9a). Keeping $$w_{RF}$$ at its maximum value provided by the high-power amplifier so that our assumptions remain valid (Figure 9), we have three time-domain parameters: the durations $$t_1$$ and $$t_2$$ of the two RF pulses, and the pulse separation $$\tau_2$$. The graph of the spectral line intensity versus one of these three parameters, the other two being constant, allows us to extract the two quadrupole parameters. Fitting two sets of experimental spectral line intensities, obtained with different values of the two constants, should provide us with the same quadrupole parameters. In practice, we apply both one- and two-pulse sequences. As the delay required to fit the one-pulse spectral line intensities is short, we use the two quadrupole parameters provided by the one-pulse experiment as initial values to fit the two-pulse sequence data.

The internal interaction throughout the two-pulse experiment is $$H_Q^{(1)}$$. The analytical expressions of the central-line intensity after the second RF pulse for spins $$I = \frac{1}{2}$$, $$\frac{3}{2}$$, and $$\frac{7}{2}$$ in a single crystal are available. Fortunately they can be calculated numerically. As the spin–lattice relaxation is not taken into account, the pulse separation $$\tau_2$$ must be short. It is of the order of magnitude of the dead-time of the receiver (typically 10–20 µs). All the density matrix elements at the end of the first RF pulse contribute to the spectral line intensity at the end of the second RF pulse. Equations (43–45) are used to calculate the central-line intensities, which are given by $$\zeta(-\frac{1}{2}, \frac{1}{2})$$ for powder samples the procedure described in section 2.1 should be used to average the quadrupole coupling $$w_Q$$.

Figure 23 shows the graphs of the central-line intensities of a spin $$I = \frac{1}{2}$$ versus the pulse duration $$t_1$$ by taking into account $$H_Q^{(1)}$$ during the excitation of the spin system by the composite-pulse sequence.\(^{70}\) Several quadrupole coupling constants have been used, which means that the sample is supposed to be a powder. The graph for $$e^2 q Q / \hbar = 0$$ is bell shaped, and that for $$e^2 q Q / \hbar = 1$$ MHz has two bell shapes of opposite signs. As with the one-pulse sequence applied to spin $$I = \frac{1}{2}$$ (Figure 14), the pulse duration that maximizes the spectral line intensity in the selective excitation is half that corresponding to the non-selective excitation condition. In contrast to the one-pulse sequence, there is no linear regime where the response of the spin system is proportional to the pulse duration, even for short pulse durations. Quantitative results based on spin population are not possible with this composite-pulse sequence. Furthermore, broad absorption lines are lost in the dead-time of the receiver, as in the one-pulse experiment. Spin-echo experiments are required in this case.

### 3.4 Solomon Echo Sequences

The FIDs that have short durations $$T_{FID}$$ are lost in the dead-time of the receiver following an RF pulse. This is the case of the FIDs of the satellite transitions whose powder pattern spreads far out from the central line. As the satellite-transition powder pattern provides us with the quadrupole parameters, we should apply the
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 24 Two-pulse $^{23}\text{Na}$ ($I = \frac{3}{2}$) spectra in a powdered NaNO$_3$ for increasing second-pulse duration $t_3$ from 1 to 13 $\mu$s, in static condition with a short pulse separation $t_2 = 10$ $\mu$s and $D_0 = 60$ s. (Reproduced from P.P. Man, ‘Determination of the Quadrupolar Coupling Constant in Powdered Samples with a Two In-phase RF Pulse Sequence in Solid-state NMR’, Chem. Phys. Lett., 168, 227–232, Copyright (1990) with permission from Elsevier Science.)

Figure 25 Experimental (filled circles) and calculated (solid line) central-line intensities of $^{23}\text{Na}$ ($I = \frac{3}{2}$) in a powdered NaNO$_3$ corresponding to Figure 24. The following parameters were used in the calculation: $t_1 = 4$ $\mu$s; $t_2 = 10$ $\mu$s; $t_3 = 1–13$ $\mu$s; $e^2qQ/\hbar = 336$ kHz; $\eta = 0$; $\omega_{RF}/(2\pi) = 46$ kHz (Reprinted from P.P. Man, ‘Determination of the Quadrupolar Coupling Constant in Powdered Samples with a Two In-phase RF Pulse Sequence in Solid-state NMR’, Chem. Phys. Lett., 168, 227–232, Copyright (1990) with permission from Elsevier Science.)

Solomon echo sequences, two-pulse sequences separated by a delay $t_2$, to recover this powder pattern. These echo sequences allow us to detect the satellite transitions as echoes located far from the second RF pulse, therefore they are not affected by the dead-time of the receiver following the second RF pulse.

The positions of the Solomon echoes and the contribution of coherences generated by the first RF pulse have been already determined for the four half-integer quadrupole spins.$^{(16)}$ The interaction considered throughout the experiment is still $H_Q^{(1)}$ (see Figure 9a). The pulse separation $t_2$ must be larger than the dead-time of the receiver but much smaller than the FID duration of the central transition $T_{\text{FID}}$ so that the Solomon echoes can be detected. There is no Solomon echo for the central transition. The Solomon echoes are satellite-transition signals. However these echoes are superimposed on the central-transition FID following the second RF pulse. In the literature, echoes observed in these conditions for $I = \frac{3}{2}$ are called quadrupole echoes. In this paper, the term “Solomon echoes” includes those observed for $I = \frac{3}{2}$.

3.4.1 Spin $I = \frac{3}{2}$

Numerous studies have been done on spin $I = \frac{3}{2}$ systems$^{(78,79)}$ but the predictions are valid only in the hard-pulse or nonselective excitation condition. That is, $H_Q^{(1)}$ has been neglected during the excitation of the spin system by the RF pulses.

3.4.1.1 Hard-pulse Excitation

Figure 26(a) is the oscillogram of the one-pulse experiment from $^{81}\text{Br}$

Figure 26 Oscillogram of Solomon echo from $^{81}\text{Br}$ ($I = \frac{3}{2}$) in KBr single crystal. The separation of the two RF pulses $P_1$ and $P_2$ is $t_2 = 180$ $\mu$s. (a) One $X$ pulse with $\pi/2$ pulse flip angle, i.e. $|X\rangle_\pi/2$; (b) the sequence $|X\rangle_{\pi/2} \tau_2 |Y\rangle_{\pi/2}$; (c) the sequence $|X\rangle_{\pi/2} \tau_2 |X\rangle_{\pi/2}$; (d) the sequence $|X\rangle_{\pi/2} \tau_2 |X\rangle_{\pi/2}$. (Reproduced by permission of Pergamon Press from G. Bonera, M. Galimberti, Solid State Commun., 4, 589–591 (1966).)
(\(I = \frac{1}{2}\)) in KBr single crystal \(^{(78)}\) two FIDs are clearly observed: the long one is that of the central transition, whereas the shorter one is for the two satellite transitions. Figure 26(b–d) shows the response of the spin system to three different experimental conditions of the Solomon echo sequence. The FID following the first RF pulse is that of the satellite transitions. This observation supports the condition that the pulse separation must be shorter than \(T_{\text{FID}}\), the duration of the central-transition FID. The observed echo, which is very sharp, is the satellite-transition signal and is located at \(t_4 = t_2\). The central-transition FID following the second RF pulse is not observed in these oscillograms due to the experimental conditions, which cause confusion with the Hahn echoes also located at \(t_4 = t_2\) and obtained with a pulse separation \(t_2 \geq T_{\text{FID}}\) (see section 3.5).

For two in-phase RF pulses, the echo amplitude \(E_{XX}^{1/2} (t_4 = t_2)\) versus the second-pulse flip angle \(\beta_3\) is the expression \(\frac{1}{4} (A + A')\) of Bonera and Galimberti (Equation 77): \(^{(78)}\)

\[
E_{XX}^{1/2} (t_4 = t_2) = \frac{1}{2} \cos^2 \frac{1}{2} \beta_3 \sin^4 \frac{1}{2} \beta_3 - \frac{3}{2} \sin^2 \frac{1}{2} \beta_3 \cos^2 \frac{1}{2} \beta_3
= - \frac{9}{8} \sin^2 \beta_3 \cos \beta_3
\]

(77)

For two RF pulses in quadrature phase, the echo amplitude \(E_{XY}^{1/2} (t_4 = t_2)\) versus the second-pulse flip angle is (Equation 78) \(^{(78)}\)

\[
E_{XY}^{1/2} (t_4 = t_2) = \frac{1}{8} \sin^2 \beta_3
\]

(78)

The thin solid line in Figure 27(a) represents the opposite of Equation (77), whereas the thin dashed line in Figure 27(b) represents the opposite of Equation (78). This complication is due to the phases of the RF pulses used, namely \([-X]_{t_2} \rightarrow [-X]_{t_4}\) for Figure 27(a) and \([-X]_{t_2} \rightarrow [Y]_{t_4}\) for Figure 27(b). They provide a simple explanation for Figure 26(b–d). For two in-phase RF pulses, the Solomon echo is a maximum when the second-pulse flip angle is \(\pi/3\) (Figure 26d and the thin solid line in Figure 27a) and zero when the second-pulse flip angle is \(\pi/2\) (Figure 26c and the thin solid line in Figure 27a). However, for two RF pulses in quadrature phase, the Solomon echo is a maximum when the second-pulse flip angle is \(\pi/2\) (Figure 26b and thin dashed line in Figure 27b).

3.4.1.2 Soft-pulse Excitation The limitation of the hard pulse or nonselective excitation is removed by taking into account \(H_0^I\) during the RF pulses. A single echo is predicted at \(t_4 = t_2\) \(^{(16,80)}\) in agreement with the results of the literature. In fact this echo represents the refocusing of satellite transitions \(I_{-3/2}^2 (t_1)\) and \(I_{-1/2}^2 (t_1)\) and \(\pm 2Q\) coherences \(I_{-1/2}^2 (t_1)\) and \(I_{-3/2}^2 (t_1)\) generated by the first RF pulse. The contributions of \(\pm 2Q\) coherences to the Solomon echo were not predicted previously, because the initial state of the spin system is \(\rho(0) = I_x\), whose matrix contains \(\pm 1Q\) coherences only. \(^{(78)}\) Phase cycling the first RF pulse and the receiver allows us to study these two contributions independently.

Figure 27 presents the \(t_4 = t_2\) Solomon echo amplitudes of a spin \(I = \frac{1}{2}\) versus the second-pulse flip angle \(\omega_{RF} t_3\) \(^{(16)}\). These echo amplitudes are associated with two in-phase RF pulses (Figure 27a) and two RF pulses

![Figure 27](image-url)
in quadrature phase (Figure 27b). The echo amplitudes decrease when the \( \omega Q/\omega RF \) ratio increases; they can be positive or negative depending on \( \omega RF/\omega I_3 \) and the \( \omega Q/\omega RF \) ratio. The graphs for \( \omega Q/\omega RF = 0.001 \) are in agreement with Equations (77) and (78), apart from the sign as already explained above. In fact the curves in Figure 27 are plotted by using the numerical procedure described in section 3.4.3.

3.4.2 Spin \( I = \frac{5}{2} \)

The spin \( I = \frac{5}{2} \) system was first studied by Solomon(13) who predicted four echoes but observed six experimentally for \( ^{127}I \) in KI. This is because he did not consider \( H_{Ox}^{(0)} \) during the RF pulses in his calculations. They are located at \( \frac{1}{4} \tau, 2\tau, 2\tau, \frac{5}{4} \tau, 3\tau, \) and \( 4\tau \); the echo positions were referenced to the first RF pulse. The \( \frac{1}{4} \tau, 2\tau, \) and \( 3\tau \) echoes were called allowed echoes, whereas \( \frac{5}{4} \tau \) and \( 4\tau \) echoes were called forbidden echoes.

3.4.2.1 Hard-pulse Excitation

The echo amplitudes for the allowed echoes, which are located at \( \tau_4 = \frac{1}{4}\tau_2, \tau_2, \) and \( 2\tau_2 \) in our notation. For two in-phase RF pulses, the echo amplitudes of the outer-satellite (\( \frac{3}{2} \) \( \leftrightarrow \) \( \frac{5}{2} \)) transition versus the second-pulse flip angle \( \beta_3 \) are given by Equations (79) and (80).(81)

\[
E_{XX}^{5/2} (\tau_4 = \frac{1}{4}\tau_2) = 20 \cos^3 \frac{1}{4} \beta_3 \sin^3 \frac{1}{4} \beta_3 \cos^2 \frac{1}{4} \beta_3
\]
\[
- 4 \cos^3 \frac{1}{4} \beta_3 \sin^2 \frac{1}{4} \beta_3 \cos \frac{1}{4} \beta_3
\]
\[
\times \sin \frac{1}{4} \beta_3 \sin \frac{5}{4} \beta_3 - 4 \cos \frac{1}{4} \beta_3
\]
\[
\times \sin \frac{3}{4} \beta_3 (79)
\]

\[
E_{XX}^{5/2} (\tau_4 = \tau_2) = 25 \cos^2 \frac{1}{2} \beta_3 \sin \frac{3}{2} \beta_3 - \cos^3 \frac{3}{2} \beta_3
\]
\[
\times \sin^2 \frac{1}{2} \beta_3 (80)
\]

Those of the inner-satellite (\( \frac{1}{2} \) \( \leftrightarrow \) \( \frac{1}{2} \)) transition versus the second-pulse flip angle \( \beta_3 \) are (Equations 81 and 82): (81)

\[
E_{XX}^{3/2} (\tau_4 = \tau_2) = 64 \left\{ \cos^2 \frac{1}{2} \beta_3 \sin^4 \frac{1}{2} \beta_3 + \frac{3}{2} \cos^2 \frac{1}{2} \beta_3
\]
\[
- \sin^2 \frac{1}{2} \beta_3 \cos \frac{1}{2} \beta_3 \cos \frac{1}{2} \beta_3
\]
\[
\times \left\{ \cos \frac{1}{2} \beta_3 + \frac{3}{2} \sin \frac{1}{2} \beta_3 \right\} \right\} (81)
\]

\[
E_{XX}^{3/2} (\tau_4 = 2\tau_2) = E_{XX}^{3/2} (\tau_4 = \frac{1}{4}\tau_2) (82)
\]

Equations (79) and (82), and the sum of Equations (80) and (81) are equivalent to the terms \( E_{1/2}, E_2, \) and \( E_4 \) of Solomon, respectively.(13)

For two RF pulses in quadrature phase, the echo amplitudes of the outer-satellite (\( \frac{3}{2} \) \( \leftrightarrow \) \( \frac{5}{2} \)) transition versus the second-pulse flip angle \( \beta_3 \) are given by Equations (83) and (84): (81)

\[
E_{XX}^{5/2} (\tau_4 = \frac{1}{4}\tau_2) = -20 \cos \frac{3}{4} \beta_3 \sin^2 \frac{1}{4} \beta_3 \cos \frac{5}{4} \beta_3
\]
\[
- 4 \cos^3 \frac{1}{4} \beta_3 \sin^2 \frac{1}{4} \beta_3 + \cos^2 \frac{3}{4} \beta_3
\]
\[
\times \sin \frac{1}{4} \beta_3 \sin \frac{5}{4} \beta_3 - 4 \cos \frac{1}{4} \beta_3
\]
\[
\times \sin \frac{3}{4} \beta_3 (83)
\]

\[
E_{XX}^{5/2} (\tau_4 = \tau_2) = 25 \cos^2 \frac{1}{2} \beta_3 \sin \frac{3}{2} \beta_3 + \cos^3 \frac{1}{2} \beta_3
\]
\[
\times \sin^2 \frac{1}{2} \beta_3 (84)
\]

Those of the inner-satellite (\( \frac{1}{2} \) \( \leftrightarrow \) \( \frac{1}{2} \)) transition versus the second-pulse flip angle \( \beta_3 \) are (Equations 85 and 86): (81)

\[
E_{XX}^{3/2} (\tau_4 = \tau_2) = 64 \left\{ \cos \frac{1}{2} \beta_3 \sin \frac{1}{2} \beta_3 + \frac{3}{2} \cos \frac{1}{2} \beta_3
\]
\[
- \sin^2 \frac{1}{2} \beta_3 \cos \frac{1}{2} \beta_3 \cos \frac{1}{2} \beta_3
\]
\[
\times \cos \frac{1}{2} \beta_3 - \frac{3}{2} \sin \frac{1}{2} \beta_3 \right\} \right\} (85)
\]

\[
E_{XX}^{3/2} (\tau_4 = 2\tau_2) = E_{XX}^{3/2} (\tau_4 = \frac{1}{4}\tau_2) (86)
\]

3.4.2.2 Soft-pulse Excitation

For any \( \omega Q/\omega RF \) ratio, six echoes have been predicted because the initial condition of the spin system is \( \rho(0) = I_2 \) instead of \( \rho(0) = I_1 \) as in the hard-pulse condition.(16,82) Three echoes, located at \( \tau_4 = \tau_2, 2\tau_2, \) and \( 3\tau_2 \), are inner-satellite transition (\( \frac{1}{2} \) \( \leftrightarrow \) \( \frac{1}{2} \)) signals:

- the \( \tau_4 = \tau_2 \) echo represents the refocusing of
  \[
  I_2^- \frac{3}{2} (t_1), I_2^- \frac{5}{2} (t_1), \frac{3}{2} I_2^- (t_1), \frac{1}{2} I_2^- (t_1)
  \]
  generated by the first RF pulse;
- the \( \tau_4 = 2\tau_2 \) echo represents the refocusing of
  \[
  I_2^- \frac{5}{2} (t_1), I_2^+ \frac{5}{2} (t_1), \frac{5}{2} I_2^- (t_1), \frac{3}{2} I_2^- (t_1)
  \]
Figure 28 Coherences in the spin $I = \frac{3}{2}$ density matrix developed at the end of the first RF pulse and refocused as Solomon echoes by the second RF pulse. Echoes are represented by thick arrows for the inner-satellite transitions ($\pm \frac{1}{2} \leftrightarrow \pm \frac{1}{2}$) and thin arrows for the outer-satellite transitions ($\pm \frac{1}{2} \leftrightarrow \pm \frac{3}{2}$). Solid-line-framed coherences contribute to the $\tau_4 = \frac{3}{2}\tau_2$ and $3\tau_2$ echoes. Dashed-line-framed coherences contribute to the $\tau_4 = \tau_2$ and $2\tau_2$ echoes. Solomon echoes are superimposed on the central-transition FID following the second RF pulse. The pulse separation is much shorter than the duration $T_{\text{FID}}$ of this FID.

- the $\tau_4 = 3\tau_2$ echo represents the refocusing of

$$I_{\frac{5}{2}}^{\frac{5}{2}}(t_1), \quad I_{\frac{5}{2}}^{\frac{3}{2}}(t_1), \quad I_{\frac{5}{2}}^{\frac{1}{2}}(t_1), \quad \text{and} \quad I_{\frac{5}{2}}^{\frac{1}{2}}(t_1)$$

The other three echoes, located at $\tau_4 = \frac{1}{2}\tau_2$, $\tau_2$, and $\frac{3}{2}\tau_2$, are outer-satellite transition ($\frac{1}{2} \leftrightarrow \frac{3}{2}$) signals; the coherences involved for each echo are given in Figure 28. In fact the 12 coherences are involved for both inner- and outer-satellite transition signals. The two forbidden echoes (the $\tau_4 = \frac{1}{2}\tau_2$ and $3\tau_2$ echoes) solely represent the refocusing of MQ ($\pm 2Q$ and $\pm 3Q$) coherences generated by the first RF pulse, whereas the four allowed echoes (the $\tau_4 = \frac{1}{2}\tau_2$, $\tau_2$, and $2\tau_2$ echoes) represent both the refocusing of SQ ($\pm 1Q$) and MQ ($\pm 2Q$ and $\pm 4Q$) coherences generated by the first RF pulse. The main drawback of Solomon echoes for spins $I = \frac{3}{2}$, $\frac{5}{2}$, and $\frac{7}{2}$ is that the Fourier transform of the time-domain signal generates distorted spectra. Direct analysis of the echoes in the time domain is necessary.

Figure 29 is the stacked plot of Solomon echoes from $^{127}\text{I} (I = \frac{3}{2})$ in powdered RbI for increasing second-pulse duration $t_1$ ranging from 1 to 20μs, obtained with the $|X\rangle\_\text{tau}\_|X\rangle$ sequence and a pulse separation $\tau_2 = 0.2$ ms. Echoes in the acquisition period are located at $\tau_4 = 0.1, 0.2, 0.3, 0.4, \text{and} 0.6$ ms.

with the following sequence:$^{(70)}$

first RF pulse: $X-Y$ $Y-X$ $Y-Y$
second RF pulse: $-X-X-X-X$ (sequence 2)
receiver: $-y-y-y-y$

Clearly the FID following the second RF pulse has been canceled by this sequence. However, the $\tau_4 = 2\tau_2$ echo is missing.
3.4.3 Numerical Procedure

For simplicity, we propose a numerical procedure for calculating the Solomon echo amplitude versus the second-pulse duration to optimize the experimental conditions for two specific echoes of a spin $I = \frac{5}{2}$ system. The method is applicable to other echoes and to other half-integer quadrupole spins, because all the echo positions and the contribution of the coherences generated by the first RF pulse have been already defined.\(^{(16)}\)

Figure 31 presents the numerical procedure for calculating the complex amplitude of the inner-satellite transition Solomon echo located at $\tau_4 = 2\tau_2$ and that of the outer-satellite transition located at $\tau_4 = \tau_2$ of a spin $I = \frac{5}{2}$. Equation (43), which describes the spin dynamics during the first RF pulse, is written in the matrix form. The initial condition for the first RF pulse is the Boltzmann density matrix $\rho(0) = I_z$, which has nonzero real values only along the main diagonal. We extract the four complex spectral line intensities $(a_{12}, a_{15}, a_{62},$ and $a_{65})$ and put them into another matrix whose elements are zeros. This matrix becomes the initial condition for the second RF pulse. The complex echo amplitudes $\zeta(\frac{1}{2}, \frac{5}{2} N_{32}$ and $\zeta(\frac{5}{2}, \frac{5}{2} N_{32})$ of the final matrix are that of the inner-satellite transition located at $\tau_4 = 2\tau_2$ and that of the outer-satellite transition located at $\tau_4 = \tau_2$, respectively. These two elements, $s_{32}$ and $s_{21}$, are $-iQ$ coherences detected by an RF coil. The other elements of this final matrix are meaningless from the point of view of Solomon echoes.

3.5 Hahn Echo Sequences

As shown in the Solomon echo sequence, taking only $H_{1}(t)$ into account throughout the experiment does not allow us to predict an echo for the central transition. As the spin–spin relaxation times are not introduced into the density matrix, the central transition, whose frequency is that of the frequency carrier, remains on resonance throughout the sequence. This suggests that the pulse separation must be much shorter than the central-transition FID duration $T_{\text{FID}}$, so that the magnetization of the central transition has no time to dephase during the pulse separation. However, by definition, the satellite transitions are off resonance and have time to dephase during the pulse separation and rephase during the acquisition period.

    0 & 0 & 0 & 0 & 0 & 0 \\
    0 & a_{62} & 0 & 0 & a_{65} & 0
\end{pmatrix} \text{Exp}(\text{it}_2 \Omega)^T
\]
To predict an echo for the central transition for pulse separation longer than \( T_{\text{FID}} \), we include, during the free precession of the spin system, the secular part of the heteronuclear magnetic dipole–dipole interaction (Equations 87 and 88):\(^{17}\)

\[
H_{\text{D(3)}} = \Phi I_z
\]

\[
\Phi = \frac{\mu_0}{4\pi} \frac{\gamma_I \gamma_S h S_z}{2(I^{-}_{-3})^3} (1 - 3 \cos^2 \theta_{I,-3})
\]

This is instead of the inhomogeneity of \( B_0 \)\(^{78,79}\) because the experiment is performed with a superconducting magnetic field whose homogeneity is very good for solid-state NMR. The interactions considered in this section are given in Figure 9(b). Only \( H_Q \) is considered during the RF pulses, an assumption that requires a strong RF pulse amplitude.

3.5.1 Hard-pulse Excitation

The \( \tau_1 = \tau_2 \) Hahn echo amplitude for the hard-pulse or nonselective excitation (\( w_Q \ll w_{\text{RF}} \)) was calculated by Mehring and Kanert.\(^{83}\) Another calculation was performed by Suemitsu and Nakajo.\(^{84}\) In these papers, two \( Y \) pulses were applied and the first RF pulse was a \( \pi/2 \) pulse so that the initial condition is \( \rho(0) = I_z \). Their conventions differ with ours but the results concerning two in-phase RF pulses do not depend on this phase. A bell-like-shape echo associated with the transition \( (m+1 \leftrightarrow m) \) is along the \( x \) axis and its amplitude is (Equations 89 and 90)

\[
E_{NS}(\tau_4 = \tau_2) = C_{NS}(m, I) \sin w_{\text{RF}} t_1
\]

\[
C_{NS}(m, I) = -\frac{3}{2} \frac{\zeta^2}{I(I+1)(2I+1)}
\]

\[
\times \{ d^{(2)}_{m,m+1}(w_{\text{RF}} t_3) \}^2
\]

where \( d^{(2)}_{m,m+1}(w_{\text{RF}} t_3) \) is the reduced Wigner rotation matrix of order \( I \). The two subscripts \( m \) and \( m+1 \) locate the matrix element. Equation (90) shows that the echo has a negative amplitude. As \( C_{NS}(m, I) \) is an even function of \( w_{\text{RF}} t_3 \), alternating the phase of the second RF pulse does not change the echo amplitude \( E_{NS}(\tau_4 = \tau_2) \). For short duration of the two RF pulses, Equation (89) becomes Equation (91):\(^{51}\)

\[
E_{NS}(\tau_4 = \tau_2) = -\frac{3}{2} \frac{\zeta^2}{I(I+1)(2I+1)} w_{\text{RF}} t_1 \left\{ \frac{1}{2} \zeta w_{\text{RF}} t_3 \right\}^2
\]

In fact the Hahn echo amplitude is the product of two functions:\(^{17}\) the first function, called the excitation function, depends on the first-pulse duration; the second function, called the transfer or conversion function, depends on the second-pulse duration.

Figure 32 shows the graphs of the transfer function of the \( \tau_4 = \tau_2 \) Hahn echo amplitudes versus the second-pulse flip angle \( \omega_{\text{RF}} t_3 \) for the spins \( I = \frac{3}{2} \) and \( \frac{3}{2} \) in the hard-pulse or nonselective excitation condition (\( w_Q \ll w_{\text{RF}} \)): solid line for the central-transition (\( -\frac{3}{2} \leftrightarrow \frac{3}{2} \)) echo; dashed line for the satellite-transition \( (\pm \frac{3}{2} \leftrightarrow \pm \frac{5}{2} \)) echoes; dotted line for the satellite-transition \( (\pm \frac{3}{2} \leftrightarrow \pm \frac{7}{2} \)) echoes. They are obtained with the numerical procedure described in section 3.5.5 or Figure 31. (Reproduced by permission of The American Physical Society from P.P. Man, Phys. Rev. B, 52, 9418–9426 (1995.).)

\[\text{Figure 32 Graphs of the transfer function of the } \tau_4 = \tau_2 \text{ Hahn echo amplitudes versus the second-pulse flip angle } \omega_{\text{RF}} t_3 \text{ for the spins } I = \frac{3}{2} \text{ and } \frac{3}{2} \text{ in the hard-pulse or nonselective excitation condition (} w_Q \ll w_{\text{RF}} \text{): solid line for the central-transition } (\frac{3}{2} \leftrightarrow \frac{3}{2}) \text{ echo; dashed line for the satellite-transition } (\pm \frac{3}{2} \leftrightarrow \pm \frac{5}{2}) \text{ echoes; dotted line for the satellite-transition } (\pm \frac{3}{2} \leftrightarrow \pm \frac{7}{2}) \text{ echoes. They are obtained with the numerical procedure described in section 3.5.5 or Figure 31.} \]

In these papers, the \( I_2 \) Hahn echo amplitudes were calculated by Mehring and Kanert.\(^{83}\) Another calculation was performed by Suemitsu and Nakajo.\(^{84}\) In these papers, two \( Y \) pulses were applied and the first RF pulse was a \( \pi/2 \) pulse so that the initial condition is \( \rho(0) = I_z \). Their conventions differ with ours but the results concerning two in-phase RF pulses do not depend on this phase. A bell-like-shape echo associated with the transition \( (m+1 \leftrightarrow m) \) is along the \( x \) axis and its amplitude is (Equations 89 and 90)

\[
E_{NS}(\tau_4 = \tau_2) = C_{NS}(m, I) \sin w_{\text{RF}} t_1
\]

\[
C_{NS}(m, I) = -\frac{3}{2} \frac{\zeta^2}{I(I+1)(2I+1)}
\]

\[
\times \{ d^{(2)}_{m,m+1}(w_{\text{RF}} t_3) \}^2
\]

where \( d^{(2)}_{m,m+1}(w_{\text{RF}} t_3) \) is the reduced Wigner rotation matrix of order \( I \). The two subscripts \( m \) and \( m+1 \) locate the matrix element. Equation (90) shows that the echo has a negative amplitude. As \( C_{NS}(m, I) \) is an even function of \( w_{\text{RF}} t_3 \), alternating the phase of the second RF pulse does not change the echo amplitude \( E_{NS}(\tau_4 = \tau_2) \). For short duration of the two RF pulses, Equation (89) becomes Equation (91):\(^{51}\)

\[
E_{NS}(\tau_4 = \tau_2) = -\frac{3}{2} \frac{\zeta^2}{I(I+1)(2I+1)} w_{\text{RF}} t_1 \left\{ \frac{1}{2} \zeta w_{\text{RF}} t_3 \right\}^2
\]
3.5.2 Selective Excitation

For selective excitation (\(w_Q \gg w_{RF}\)) the maximum of the echo amplitude is given by Equations (92) and (93):\(^{(31)}\)

\[
E_i(t_f = t_Z) = C_s(m, I) \sin \zeta w_{RF} t_f \sin^2 \frac{1}{2} \zeta w_{RF} t_Z
\] (92)

\[
C_s(m, I) = -\frac{3}{2} \frac{\zeta}{(I+1)(2I+1)} \sin^2 \frac{1}{2} \zeta w_{RF} t_Z
\] (93)

For a spin \(I = \frac{1}{2}\) system, \(\zeta = 1\) (see Table 1), and Equation (92) reduces to Equation (94):

\[
E_i(t_f = t_Z) = -\sin w_{RF} t_f \sin^2 \frac{1}{2} w_{RF} t_Z
\] (94)

The subscript \(s\) in Equation (94) is meaningless in the present case of \(I = \frac{1}{2}\), because the latter has only two energy levels. Figure 35 is the oscillogram of proton \(^1\)H \((I = \frac{1}{2})\) in glycerine showing an FID following the first RF pulse, an FID following the second RF pulse and the Hahn echo.\(^{(14)}\) The latter two signals will be separated if the pulse separation is larger than \(2T_{FID}\). The Hahn echo is due to the inhomogeneity of conventional iron \(B_0\). With modern spectrometers, alternating the phase of the second RF pulse will cancel the FID following the second RF pulse. As a result, the pulse separation can be reduced from \(2T_{FID}\) to \(T_{FID}\) – the full echo is still observed but with larger amplitude than that observed when the pulse separation is \(2T_{FID}\). These experimental conditions remain valid for half-integer quadrupole spins. Figure 36
shows the imaginary and real parts of the 23Na echo in an aqueous solution of NaCl versus the second-pulse flip angle.\(^{(70)}\) The homogeneity of the superconducting \(B_0\) was reduced by using the \(z\) shim. The echo amplitude increases with the second-pulse flip angle, in agreement with Equation (94).

Figure 37 is the \(^{87}\)Rb \((I = \frac{1}{2})\) Hahn echo in powdered pyrochlore RbNb$_2$O$_5$F.\(^{(85)}\) In this compound the EFG around the rubidium atoms is very strong. The variation of the echo amplitude versus the second-pulse duration is described by Equation (92).

As \(C_i(m, I)\) is also an even function of \(w_{\text{RF}}t_3\), alternating the phase of the second RF pulse does not change the echo amplitude \(E_i(\tau_4 = \tau_2)\). As alternating the phase of the second RF pulse does not change the echo amplitude in both nonselective and selective excitations, it must be true for any excitation condition. Indeed analytical results on spin \(I = \frac{3}{2}, \frac{5}{2}\) (55, 58) and \(\frac{1}{2}\) \(^{(51)}\) support this observation.

If both pulse durations are short Equation (95) holds:

\[
E_i(\tau_4 = \tau_2) = E_{\text{NS}}(\tau_4 = \tau_2) = - \frac{3}{2I(I + 1)} w_{\text{RF}} t_3 \left(\frac{1}{2}w_{\text{RF}} t_3\right)^2
\]

Therefore the echo amplitude is independent of \(w_O\) but depends linearly on the first-pulse duration and quadratically on the second-pulse duration.\(^{(51)}\) This excitation condition is useful for spin population determination in single crystals as well as in powders.

3.5.3 Soft-pulse Excitation for Spin \(I = \frac{3}{2}:\) Piezoelectric Signal Suppression

The secular part of the heteronuclear magnetic dipole–dipole interaction during free precession of the spin system and the first-order quadrupole interaction throughout the experiment are now considered (Figure 9b). For a spin \(I = \frac{3}{2}\) system, three Hahn echoes are predicted and observed: two central-transition echoes located at \(\tau_4 = \tau_2\) and \(\tau_4 = 3\tau_2\), and the satellite-transition echoes located at \(\tau_4 = 2\tau_4\).\(^{(17, 88)}\) The \(\tau_4 = \tau_2\) Hahn echoes are the refocusing of 1Q coherences generated by the first RF pulse, namely

\[
-i \left(\frac{3}{2}I_3 - 4I_2 \right) (t_1) /I_2 \left(\frac{3}{2}I_3 - 4I_2 \right) (t_1)
\]

The \(\tau_4 = 3\tau_2\) echo is the refocusing of the 3Q coherence generated by the first RF pulse,

\[
-i \left(\frac{3}{2}I_3 - 3I_2 \right) (t_1)
\]

Figure 38 is the oscillogram of the 53Cr \((I = \frac{3}{2})\) echoes observed in CdCr$_2$Se$_4$.\(^{(90)}\) The positions of the two echoes are referenced to the first RF pulse, that is, 2\(\tau\) and 4\(\tau\) instead of \(\tau_2\) and 3\(\tau_2\).

Figure 39 presents the graphs of the transfer function of the central transition versus the second-pulse flip angle for several \(w_Q/w_{\text{RF}}\) ratios.\(^{(17)}\) They are obtained by using the procedure described in section 3.5.5. The graph for \(w_Q/w_{\text{RF}} = 0\) is in agreement with that of Mehring and Kanert\(^{(83)}\) or Equation (90). The graph for \(w_Q/w_{\text{RF}} = 20\) is in agreement with Equation (93). The piezoelectric signals are observed when a ferroelectric material\(^{(91)}\) is studied in single crystal form. In the past several methods have been used for attenuating these piezoelectric signals. The simplest but least interesting method is to grind the single crystal into powder so that the centers of gravity of the positive and negative charges are merged. Alternatively, the single crystal can

\[\text{Figure 37 Experimental } ^{87}\text{Rb } (I = \frac{1}{2}) \text{ Hahn echo (in the time domain) of powdered pyrochlore RbNb}_2\text{O}_5\text{F for } t_1 = 1 \text{ to } 24 \mu s \text{ by steps of } 1 \mu s. \text{ These echoes are acquired with the } \{X\} \Rightarrow \{\pm X\} \text{ sequence; } t_1 = 6 \mu s, \tau_2 = 300 \mu s, D_0 = 1 \text{ s, and } T_{\text{FWHM}} = 300 \mu s. \text{ The RF pulse amplitude is } w_{\text{RF}}/(2\pi) = 21 \text{ kHz, corresponding to a } \pi/2 \text{ pulse duration of } 12 \mu s.\]
be put into oil, CCl₄ or paraffin to attenuate the piezoelectric signals. Shielding the sample with an extra coil inside the RF coil is also effective.\(^{(91)}\)

Hahn echo sequences were applied to cancel these spurious signals. Five sequences were tested for the proposals. Figure 40 presents the efficiency of these sequences.\(^{(92)}\) Clearly sequence (e) gives the best result. Sequence (a), which consists of two RF pulses of the same phase, and sequence (c), which is sequence (a) where the phase of the second RF pulse alternates, provide negative echoes. Sequence (b), which consists of two RF pulses in quadrature phase, and sequence (d), which is sequence (b) where the phase of the second RF pulse alternates, provide positive echoes. Sequence (e) is sequence (c) followed by sequence (d) whose receiver phase has opposite phase to make the echo negative so that the echoes co-add.\(^{(93)}\)

first RF pulse: \[ +X \quad +X \quad +X \quad +X \]

second RF pulse: \[ +X \quad -X \quad +Y \quad -Y \quad \text{(sequence e)} \]

receiver: \[ +x \quad +x \quad -x \quad -x \]

The efficiency of sequence (e) to cancel the piezoelectric signals does not depend on the two pulse durations.\(^{(94)}\) In fact this sequence also cancels the spurious signals generated by the NMR probe head. We have used this sequence to observe \(^{131}\)Xe \((I = \frac{5}{2})\) physisorbed in NaY zeolite (Figure 41).\(^{(94)}\)

3.5.4 Soft-pulse Excitation for Spin I = \(\frac{5}{2}\)

Figure 42 shows the coherences developed at the end of the first RF pulse and refocused as Hahn echoes by the second RF pulse.\(^{(17)}\) Six echoes have been predicted: three as the central-transition echo located at \(\tau_4 = \tau_2, 3\tau_2\), and \(5\tau_2\); two as the inner-satellite transition echoes located at \(\tau_4 = \tau_2\) and \(3\tau_2\); and one echo as the outer-satellite transition echo located at \(\tau_4 = 2\tau_2\). These echoes are the refocusing of

\[ -i \begin{bmatrix} \frac{1}{2} & -1 \end{bmatrix} (t_1), \quad \begin{bmatrix} \frac{3}{2} & -1 \end{bmatrix} (t_1), \quad \begin{bmatrix} \frac{5}{2} & -1 \end{bmatrix} (t_1), \quad \begin{bmatrix} \frac{7}{2} & -1 \end{bmatrix} (t_1) \]

respectively. In practice, only the \(\tau_4 = \tau_2\) Hahn echoes are observed.

Figure 43 presents the one-pulse spectra of \(^{27}\)Al \((I = \frac{5}{2})\) in a polycrystalline sample of KAl(SO₄)₂·12H₂O.\(^{(89)}\) The satellite-transition powder patterns are distorted by the dead-time of the receiver. However, Figure 44 presents the Hahn echo spectra of \(^{27}\)Al \(I = \frac{5}{2}\) in the same sample;\(^{(89)}\) the satellite-transition powder patterns are reconstructed only when the second pulse duration is short. For longer second-pulse durations, the powder patterns differ from what is expected. In this compound, an aluminum atom is hexacoordinated to six water
molecules. The heteronuclear magnetic dipole–dipole interaction of aluminum with 12 protons is much larger than the homonuclear magnetic dipole–dipole interaction of aluminum with its surrounding aluminum atoms. In other words, the Hamiltonians (Figure 9b) required for the formation of Hahn echoes are verified for aluminum atoms in this compound.

3.5.5 Numerical Procedure

The Hahn echo amplitude is the product of two functions:(17) the first function, called the excitation function, depends on the first-pulse duration \( t_1 \); the second function, called the transfer or conversion function, depends on the second-pulse duration \( t_3 \). The positions of the central- and satellite-transition Hahn echoes and the coherences generated at the end of the first RF pulse and involved in the Hahn echo amplitude have been established for the four half-integer quadrupole spins.(17)

Figure 45 presents the numerical procedure for calculating the \( \tau_4 = t_2 \) Hahn echo complex amplitude \( (s_{43}) \) of the central transition in a spin \( I = \frac{3}{2} \) system. The first part of this procedure concerning the first RF pulse is identical to that proposed for Solomon echoes (Figure 31). However, only one coherence or complex spectral line intensity,

\[
a_{34} = -i \left( s^{1/2}_{43}(s) \right)
\]

contributes to the initial density matrix for the second RF pulse to calculate the transfer function, which is defined by \( \xi(1, -1) \text{Im}(s_{43})/\text{Im}(a_{34}) \), where Im means the imaginary part. The other elements of the matrix \( s \) are meaningless. Figure 39 shows the graphs of the transfer function for spin \( I = \frac{3}{2} \) and \( \frac{5}{2} \), obtained with the numerical procedure; one important feature of these transfer functions is that they are always positive or negative, whereas Solomon echoes change sign with the second-pulse duration. For short pulse duration \( t_3 \), the transfer function is independent of the quadrupole coupling \( w_Q \) and varies quadratically with \( t_3 \) (see Equation 95).

3.5.6 Any Spin in a Static Sample

The interactions considered during free precession define the nature and position of the echoes, whereas the interactions considered during the RF pulses affect the echo amplitude. However, the powder patterns are affected by the two pulse durations.

In particular, when \( H_Q^{(2)} \) is taken into account during free precession (Figure 9c), the secular term of the heteronuclear magnetic dipole–dipole interaction need not be considered because \( H_Q^{(2)} \) is an odd function of \( I_z \) (Equation 7). In other words, \( H_Q^{(2)} \) contains a term \( I_z \) (Equation 9) that allows the dephasing and the refocusing of the central-transition coherence. Dumazy and colleagues(95) have shown, in the case of \( I = \frac{3}{2} \), that only the \( \tau_4 = t_2 \) Hahn echoes are observable.

So far homonuclear magnetic dipole–dipole interaction has been neglected. In fact this interaction, present in a static sample, generates other echoes,(96) which is why the samples used to illustrate theoretical results are so specific: chlorine in NaCl, rubidium in...
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 42 Coherences of the spin $I = \frac{5}{2}$ density matrix developed at the end of the first RF pulse and refocused as Hahn echoes by the second RF pulse. Echoes are represented by thick arrows for the central transition ($-\frac{5}{2} \leftrightarrow \frac{1}{2}$), medium arrows for the inner-satellite transition ($\frac{5}{2} \leftrightarrow \frac{3}{2}$), and a thin arrow for the outer-satellite transition ($\frac{5}{2} \leftrightarrow \frac{7}{2}$). Coherences and corresponding echoes located at $t_4 = t_2, 3t_2$, and $5t_2$ are connected by arrows (solid line for 1Q, dashed line for 3Q, and dot-dashed line for 5Q). (Reproduced by permission of The American Physical Society from P.P. Man, Phys. Rev. B, 52, 9418–9426 (1995).)

Figure 43 Effect of the dead-time of the receiver on the satellite-transition powder pattern: one-pulse spectra of $^{27}$Al ($I = \frac{5}{2}$) in a polycrystalline sample of KAl(SO$_4$)$_2$·12H$_2$O. The pulse duration $t_1$ increases from 0.5 to 6 $\mu$s by steps of 0.5 $\mu$s. (Reprinted from P.P. Man, E. Duprey, J. Fraissard, P. Tougne, J.-B. d’Espinose, ‘Spin-$\frac{5}{2}$ Hahn Echoes in Solids’, Solid State NMR, 5, 181–188, Copyright (1995), with permission from Elsevier Science.)

Figure 44 Effect of the second-pulse duration on the spectral line intensity and the shape of the spectrum, Fourier transform of half of the Hahn echo: the $^{27}$Al ($I = \frac{5}{2}$) spectra of KAl(SO$_4$)$_2$·12H$_2$O, acquired with the sequence $f_{X}g_{t}f_{X}g_{t}$, $t_2 = 160$ $\mu$s and $T_{1}$ = 1 $s$; $T_{10}$ = 200 $\mu$s. The second-pulse duration $t_3$ increases from 0.5 to 6 $\mu$s by steps of 0.5 $\mu$s. (Reprinted from P.P. Man, E. Duprey, J. Fraissard, P. Tougne, J.-B. d’Espinose, ‘Spin-$\frac{5}{2}$ Hahn Echoes in Solids’, Solid State NMR, 5, 181–188, Copyright (1995), with permission from Elsevier Science.)

3.5.7 Any Spin $I$ in a Fast-rotating Sample

In this and the following section, the sample rotates at the magic angle $\theta_m$ under rapid conditions during the two-pulse experiment. The following interactions (Equations 96 and 97) are taken into account to predict the spin dynamics (Figure 9d):

$$H_{\text{int}} = H_{\text{CS}} + H_{\text{Q}}^{2\text{fast MAS}}$$

(Equations 96 and 97)
Figure 45 Numerical procedure for calculating the complex amplitude s_{i3} of the central-transition τ₂ Hahn echo of a spin I = \frac{1}{2}, valid for static condition whatever the pulse durations or fast MAS condition with short pulse durations. The initial condition for the first RF pulse is the Boltzmann density matrix containing nonzero but real diagonal elements. The initial condition for the second RF pulse is the matrix containing only one nonzero but complex element, a_{ii}, provided by the density matrix of the first RF pulse. The other parameters are identical to those of Figure 31.

during the free precession of the spin system, because \( H_{Q}^{(1)} \) = 0 in the fast condition; and

\[
H = H_{Q}^{(1)} + H_{RF}
\]  

(97)
during the RF pulses. The static Hamiltonian is considered during the RF pulses, which means that the pulse durations must be short enough so that the rotor appears static during the excitation of the spin system.

3.5.7.1 \text{p-Quantum Line Shift} In theoretical study, the isotropic chemical shift \( \delta_{C}^{(iso)} \) of a line located at \( w_L \) is referenced relative to \( w_C \). The contribution of \( H_{C} \) (Equation 38) to the absorption line position with respect to \( w_C \) is defined by Equation (98):

\[
w_{r,c}^{(iso)} = \langle r | H_{C} | r \rangle - \langle c | H_{C} | c \rangle = -(r - c)\omega_{C}^{2}\delta_{C}^{(iso)}
\]  

(98)
The analytical expression of \( w_{r,c}^{(2,\text{fast \ MAS})} \) is unknown but is defined by the second-order quadrupole shift \( w_{r,c}^{(2,\text{fast \ MAS})} \) of the \( (r - c) \)-quantum absorption line relative to \( w_L \) (Equation 99):

\[
w_{r,c}^{(2,\text{fast \ MAS})} = \langle r | H_{Q}^{(2,\text{fast \ MAS})} | r \rangle - \langle c | H_{Q}^{(2,\text{fast \ MAS})} | c \rangle
\]  

(99)

We confine ourselves to investigate the on-resonance symmetrical coherences. On-resonance means “in the second main diagonal of the density matrix”. Symmetrical means “connecting \( |r\rangle \) with \( |-r\rangle \)”, that is, \( c = -r \). In this case, the coherence order is \( p = 2r \) and\(^{(18)}\)

\[
w_{p/2,-p/2}^{(2,\text{fast \ MAS})} = \frac{\delta_{Q}}{w_{L}} \left[ \frac{1}{2} C_{0}(I, p) B_{00}(\eta) + \frac{1}{2} C_{2}(I, p) \right.
\]

\[
\times \left( B_{40}(\eta) d_{04}^{4}(\beta_{1}) + 2 B_{42}(\eta) d_{24}^{4}(\beta_{1}) \cos 2\alpha_{1}
\]

\[
+ 2 B_{44}(\eta) d_{44}^{4}(\beta_{1}) \cos 4\alpha_{1} \right) \rho_{4}(\cos \theta_{m})
\]

\]  

(100)
The parameters \( C_{0}(I, p) \), \( C_{2}(I, p) \), \( \lambda(I, p) \), and \( k(I, p) \), used in Equation (100) and given values in Table 2, are defined in Equations (101–104):

\[
C_{0}(I, p) = p \{ I(I + 1) - \frac{1}{2} p^{2} \}
\]  

(101)

\[
C_{2}(I, p) = p \{ 18 I(I + 1) - \frac{17}{2} p^{2} - 5 \}
\]  

(102)

\[
\lambda(I, p) = \frac{C_{0}(I, p)}{C_{0}(I, -1)}
\]  

(103)

\[
k(I, p) = \frac{C_{2}(I, p)}{C_{2}(I, -1)}
\]  

(104)
The other parameters in Equation (100) have been defined previously.\(^{(18)}\) The function \( \xi_{-1/2,1/2} \) depends on orientation parameters. The second-order quadrupole shift of the center of gravity of the central-transition

\end{table}
powder pattern \( (p = 1) \) \( w_{-1/2,1/2}^{2\text{iso}} \) is given by Equation (36). If \( \eta \) cannot be determined by line-shape analysis, the parameter \( C_{Qn} \) relating \( \eta^2 Q \) to \( \eta \) (Equation 105),

\[
C_{Qn} = \frac{\eta^2 Q}{\hbar} \sqrt{\frac{1}{2} \eta^2 + 1}
\]

\[
= I(2I - 1) \frac{w_L}{2\pi} \frac{40}{3 \{I(I + 1) - \frac{1}{4}\}} \left( \frac{w_{-1/2,1/2}^{2\text{iso}}}{w_0} \right)
\]

(105) derived from Equations (12) and (36), is used for characterizing a material. This is especially the case for materials having featureless NMR line shapes in the \( F_2 \) dimension, such as glasses. As \( H_{CS} \) is also considered during free precession of the spin system, the total shift \( w_{p/2-p/2}^{\text{fast MAS}} \) of the \( pQ \) absorption line is given by Equation (106),

\[
w_{p/2-p/2}^{\text{fast MAS}} = \lambda(I, p)w_{-1/2,1/2}^{2\text{iso}} - k(I, p)\xi_{-1/2,1/2} - pu_{c}^{\text{iso}} \]

(106)

which is the sum of Equations (98) and (100).

3.5.7.2 Phase Modulation of the Echo and Antiecho Amplitudes The amplitude of the central-transition FID during the acquisition period \( \tau_4 \) is described by Equation (107):\(^{18}\)

\[
- \frac{1}{2} \rho^s(t_1, t_2, t_3, \tau_4) \frac{1}{2} = \exp(-ir_4w_{-1/2,1/2}^{\text{fast MAS}})
\]

\[
\times \sum_{p=-2l}^{2l} \frac{1}{2} \rho^s_p(t_1, t_2) \frac{1}{2} \exp(-ir_2w_{p/2-p/2}^{\text{fast MAS}})
\]

\[
= \sum_{p=-2l}^{2l} \frac{1}{2} \rho^s_p(t_1, t_2) \frac{1}{2} \exp(-i(t_4 + \lambda(I, p)r_3)w_{-1/2,1/2}^{2\text{iso}})
\]

\[
\times \exp(-i(t_4 - k(I, p)r_3)\xi_{-1/2,1/2})
\]

\[
\times \exp(-i(t_4 - pr_2)u_{c}^{\text{iso}})\]

(107)

Echoes appear at the positions \( \tau_4 \) defined by the three conditions of Equation (108):

\[
\tau_4 + \lambda(I, p)r_3r_2 = 0, \quad \tau_4 - k(I, p)r_3r_2 = 0, \quad \tau_4 - pr_2 = 0
\]

(108)

By convention the refocusing of coherence occurring after the second RF pulse is an echo, whereas that occurring before the second RF pulse is an antiecho. They are central-transition signals. As \( \lambda(I, p) \) and \( k(I, p) \) are odd functions of \( p \), the positions of the echoes and antiechoes are symmetrical with respect to \( \tau_4 = 0 \).

For a given \( I \) and \( p \), the amplitudes of the echo and antiecho located at \( \tau_4 = k(I, p)r_3r_2 \) are phase modulated as in Equations (109) and (110):

\[
- \frac{1}{2} \rho^s(t_1, t_2, t_3, \tau_4 = k(I, p)r_3r_2) \frac{1}{2} = \exp(-ir_2w_{F1}(I, p))
\]

(109)

\[
w_{F1}(I, p) = (k(I, p) + \lambda(I, p))w_{-1/2,1/2}^{2\text{iso}}
\]

(110)

The term \( w_{F1}(I, p) \) depends on two isotropic shift values, \( w_{-1/2,1/2}^{2\text{iso}} \) and \( \delta_{CS}^{\text{iso}} \), and is therefore independent of the nature of the sample (single crystal or powder).

As a result, \( w_{F1}(I, p) \) is not broadened by orientation-dependent parameters when the sample is polycrystalline. Equation (110) plays a crucial role in MQ/MAS methodology. The density matrix \( \rho^p(t_1, t_2) \) in Equations (107) and (109) is defined by\(^{17}\)

\[
\rho^p(t_1, t_2) = T \exp(-i\Omega T)\rho^p(t_1)T \exp(i\Omega T)T^\dagger
\]

(111)

Equation (111) differs from Equation (43) by the initial density operator, \( \rho^p(t_1) \) instead of \( \rho(0) \). In fact Equation (111) has been used within the two numerical procedures described in sections 3.4.3 and 3.5.5. Similarly, the amplitudes of echo and antiecho located at \( \tau_4 = -\lambda(I, p)r_3r_2 \) are phase modulated by

\[
w_{F1}(I, p) = -(k(I, p) + \lambda(I, p))\xi_{-1/2,1/2}
\]

(112)

Those of the echo and antiecho located at \( \tau_4 = pr_2 \) are phase modulated by

\[
w_{F1}(I, p) = (p + \lambda(I, p))w_{-1/2,1/2}^{2\text{iso}} + (p - k(I, p))\xi_{-1/2,1/2}
\]

(113)

Equations (112) and (113) depend on \( \xi_{-1/2,1/2} \), which is a function of orientation parameters. In a powder sample, this dependence may destroy the echoes and antiechoes.

For the \( \tau_4 = r_2 \) Hahn echo, which is the refocusing of the 1Q coherence developed at the end of the first RF pulse, we have from Table 2: \( p = 1 \), \( k(I, 1) = 1 \), and \( \lambda(I, 1) = -1 \), that is, \( w_{F1}(I, 1) = 0 \) for Equations (110), (112) and (113). The amplitudes of the \( \tau_4 = r_2 \) Hahn echo (1Q echo) and the \( \tau_4 = -r_2 \) Hahn antiecho (−1Q antiecho) are not phase modulated. The MQ/MAS method (see section 3.5.8), if it is applied to the \( \tau_4 = r_2 \) Hahn echo, will not split peaks in the \( F_1 \) dimension.

Figure 46 presents the echoes for the spin \( I = \frac{3}{2} \) system.\(^{49}\) The echo located at \( \tau_4 = \frac{7}{2}r_2 \), which is the refocusing of the −3Q coherence developed at the end of the first RF pulse, is called −3Q echo and is close to the 1Q echo. The latter has an amplitude much
larger than that of the −3Q echo. As the 3Q and −3Q coherences at the end of the first RF pulse have opposite amplitudes, Figure 47 only shows the graph of the imaginary part, 

$$I_y^{3/2} = \text{Tr} \rho(t_1) I_y^{3/2}$$

of the 3Q coherence for a spin $I = \frac{3}{2}$, for three values of quadrupole coupling. Their maxima are obtained with longer pulse duration than that used for −1Q coherence. As far as the pulse durations are short enough, the transfer function can be calculated by using the numerical procedure described in section 3.5.5.

Phase cycling the RF pulse and the receiver is required to cancel the 1Q echo and the −1Q antiecho without affecting the −3Q echo and the 3Q antiecho of an $I = \frac{3}{2}$ system. The other method is to apply a pulsed magnetic field gradient to cancel the unwanted echo and antiecho.

**Figure 46** On-resonance coherences in the second main diagonal of the spin $I = \frac{3}{2}$ density matrix developed at the end of the first RF pulse and refocused as Hahn echo by the second RF pulse in rapid MAS conditions: the thick arrow at $t_4 = t_5$ is the 1Q Hahn echo, the medium arrow at $t_4 = \frac{2}{3}t_2$ is the echo observed in the 3Q MAS experiment, and the thin arrows at $t_4 = 3t_2$ are echoes not often observed. On-resonance coherences and corresponding echoes are connected by arrows. Antiechoes are not shown. (Reproduced by permission of The American Physical Society from P.P. Man, Phys. Rev. B, 55, 8406–8424 (1997).)

**Figure 47** Graph of the excitation function (or the imaginary part) of the 3Q on-resonance coherence for a spin $I = \frac{3}{2}$, generated by the first RF pulse in a Hahn echo sequence consisting of two $-X$ pulses, versus the first-pulse duration $t_1$ for $\omega_{RF}/(2\pi) = 50$ kHz and three values of $\omega_{Q}/(2\pi)$: thin line for 10 kHz, medium line for 50 kHz, and thick line for 200 kHz. ### 3.5.8 Multiple Quantum/Magic-angle Spinning Under Rapid Conditions

Frydman and colleagues introduced the MQ/MAS methodology, which is based on 2-D methods. The MQ/MAS methodology takes advantage of the properties of the MQ coherences to generate high-resolution isotropic spectra along the $F_1$ dimension, giving the number of different crystallographic sites in a compound when the conventional 1-D MAS experiment provides overlapping absorption lines. Among all the coherences generated by the first RF pulse, the specific MQ coherences are detected selectively by phase cycling the RF pulses and the receiver in the Hahn echo sequence. A sheared 2-D MQ/MAS spectrum represents the correlation of a specific MQ coherence in the $F_1$ dimension with an SQ coherence in the $F_2$ dimension. The 2-D spectrum associated with a single site consists of a single peak, an MQ-filtered central-transition peak (simply called the peak in the remainder of this article). Provided that the sheared 2-D MQ/MAS spectrum is labeled in chemical shift units and the zero ppm positions in both axes are defined, knowledge of the two observed chemical shifts of the center of gravity $\delta_{G1}^{(obs)}$ and $\delta_{G2}^{(obs)}$ of a peak in the two dimensions ($F_1$ and $F_2$) enables determination of the true isotropic chemical shift $\delta_{CS}^{(iso)}$ of an absorption line. The asymmetry parameter $\eta$ may be determined by the line shape of the cross-section of a peak parallel to $F_2$.

The rotor spinning axis is at the magic angle throughout the experiment. Thus a standard MAS probehead suffices for the experiment, but the NMR spectrometer must be equipped with a digital dephaser of the RF
pulses or a pulsed magnetic field gradient probe. The optimum experimental conditions for MQ/MAS experiments are strong RF pulses, small offset, and high rotor spinning rate. Quantitative results on spin populations are not obvious, but are possible under particular conditions. Conventional 1-D MAS spectra obtained with short pulse durations allow determination of the spin populations if the absorption lines are not overlapping (section 3.1.4.1). If not, the MQ/MAS methodology can be used to determine the number of peaks or crystallographic sites, their true isotropic chemical shifts, and the quadrupole parameters. Thanks to these data, the 1-D MAS spectra can be simulated to obtain the spin population of each site.\(^{(100)}\)

3.5.8.1 Selective Detection of the ±3Q Coherences To cancel the 1Q echo and \(−1Q\) antiecho in the two-pulse sequence, the standard way is to cycle the RF pulse phases and that of the receiver. We have already applied a mathematical approach.\(^{(49)}\) Here we apply a diagramatic approach. Figure 48(a–c) shows the positions of the on-resonance coherences (±1Q and ±3Q) at the end of the first RF pulse when the RF field \(B_\text{1}\) is positioned at 0°, 120°, and 240° in the rotating frame. The ±3Q coherences remain along the \(y\) axis of the receiver, in agreement with Equation (64). Cycling according to these three cases co-adds the ±3Q coherences and cancels the ±1Q coherences. However the zero-quantum coherences are not affected by this RF pulse cycling and are also co-added; they will contribute to the FID following the second RF pulse. To cancel the zero-quantum coherences, \(B_\text{1}\) is positioned at 90°, 180°, and 300° (Figure 48d–f). The ±1Q coherences are canceled but ±3Q coherences are along the \(−y\) axis of the receiver. To co-add the contributions of the ±3Q coherences to those of Figure 48(a–c) the receiver phase must be set to \(−y\). In this case the contributions of the zero-quantum coherences are also canceled. As a result, these six phase-cyclings of the first RF pulses and the receiver allow selective detection of the ±3Q coherences generated by the first RF pulse.\(^{(101)}\)

3.5.8.2 Experimental and Data Processing From now on, standard notation for 2-D NMR is used: \(t_1\) (the pulse separation) is the experimental evolution period, and \(t_2\) is the acquisition period. First, the echo signal is optimized by systematic variation of each pulse duration.\(^{(99)}\) Then, signal acquisition in the 2-D experiment occurs as follows: for each increment \(\Delta t_1\) of the experimental evolution period, the time-domain signals appearing after the second RF pulse are acquired in the simultaneous mode. To obtain a pure 2-D absorption spectrum, the hypercomplex method\(^{(102)}\) for generating quadrature detection in the \(t_1\) domain is applied during the signal acquisition. Sometimes the increment of the experimental evolution period is synchronized with the rotor spinning rate.\(^{(103)}\)

Double Fourier transform of the experimental data from \(F(t_1, t_2)\) to \(F(w_1, w_2)\) via \(F(t_1, t_2)\) yields a pure 2-D absorption spectrum but tilted. However a shearing transformation of \(F(t_1, w_2)\) yields a powder pattern along the \(F_2\) dimension, and a high-resolution featureless line shape in the \(F_1\) dimension. The sheared 2-D spectrum becomes a 2-D isotropic/anisotropic correlation spectrum. More details on the shearing transformation can be found in literature.\(^{(49,98,102)}\)

3.5.8.3 Labeling the \(F_1\) Axis in the Frequency Unit The spectral width (SW) in the \(F_1\) dimension (SW1) of a 2-D MQ/MAS spectrum is equal to the inverse of the increment of the evolution period. Unfortunately, two definitions of the evolution period appear in the literature, giving two conventions for scaling in frequency units the SW1. The first convention (Cz) considers the experimental evolution period as the evolution period,\(^{(98,104)}\) therefore \(\text{SW1}_\text{Cz} = 1/(\Delta t_1)\). The second convention (Ck) considers the position of the echo relative to the first RF pulse, equal to \((1+k)\) times the experimental evolution period, as the evolution period,\(^{(102,105)}\) therefore \(\text{SW1}_\text{Ck} = 1/((1+k)\Delta t_1)\). This article uses the Cz convention, because both conventions have been compared previously.\(^{(49)}\)

If we synchronize the increment of the experimental evolution period \(\Delta t_1\) with the inverse of the rotor spinning rate \(v_\text{rotor}\), that is if \(\Delta t_1 = 1/v_\text{rotor}\), then \(\text{SW1}_\text{Cz} = v_\text{rotor}\). Spinning sidebands along the \(F_1\) dimension, located outside the SW1\(_{\text{Cz}}\), will be folded back onto the centerband, increasing the spectral line intensity and improving the line shape of the centerband.\(^{(103)}\) However,
Table 3 Relationships of various parameters of chemical shift (CS), offset, shift, and center of

gravity (CG) expressed with respect to the carrier frequency \( w_c \), the coherence order \( p \) of the
echo located at \( k \), and \( \lambda \) (Equation 103) used in this paper and those of Amoureux and
Fernandez\(^{106}\) for sheared 2-D MQ/MAS spectra. (\( w_{F1}(I, p) = (k + \lambda)w_c^{21/2} + (k - p)\delta_{CG}^{\text{iso}}w_c \),
k \equiv R in Amoureux and Fernandez’s notation.)

\( a \) Observed chemical shift of the center of gravity of a peak in the \( F_2 \) dimension.
\( b \) Observed chemical shift of the center of gravity of a peak in the \( F_1 \) dimension.
\( c \) Isotropic chemical shift.
\( d \) Second-order quadrupole shift of the central line expressed as chemical shift.
\( e \) Offset of the frequency carrier with respect to the aqueous solution in the \( F_2 \) dimension.
\( f \) Chemical shift of the frequency carrier with respect to the aqueous solution in the \( F_1 \) dimension.
\( g \) Offset of the frequency carrier with respect to the aqueous solution in the \( F_2 \) dimension.

As the observed chemical shift of the center of gravity of a peak relative to \( w_c \) (Equation 114) for the \( Cz \) convention is given by Equation (116):

\[
\delta_{\text{G1}}^{\text{iso}} = (k - p)\delta_{\text{obs}}^{\text{iso}} + (k + \lambda)\frac{w_{F2}^{21/2}}{w_c}
\]  

(116)

As the observed chemical shift of the center of gravity of the central-transition powder pattern relative to \( w_c \) along the \( F_2 \) dimension \( \delta_{\text{G1}}^{\text{obs}} \) is given by Equation (37), the latter and Equation (116) allow deduction of the true isotropic chemical shift of a peak relative to \( w_c \) (Equation 117):

\[
\delta_{\text{G1}}^{\text{obs}} = \frac{(k + \lambda)\delta_{\text{obs}}^{\text{iso}} - \delta_{\text{G1}}^{\text{obs}}}{p + \lambda} = \frac{10\delta_{G2}^{\text{iso}}}{27\lambda} - \frac{1}{p + \lambda} \delta_{G1z}^{\text{obs}}
\]

(117)
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

36

\[ \Omega_{F_1} = (k - p)\Omega_{F_2} \]  \quad (118)

Now we know the position (Equation 112) of a peak relative to \( w_c \) and the offset (Equation 118) of \( w_c \) relative to the aqueous solution in the \( F_1 \) dimension. Therefore we know the position of the peak relative to the aqueous solution, which is what we are looking for. As the offsets in both dimensions are known, Equations (37), (116) and (117) remain valid even when the observed chemical shifts of the center of gravity of a peak along the two axes are referenced to an aqueous solution instead of \( w_c \).

We can also deduce \( w_c^{(2)iso} \) from Equations (37) and (116):

\[
\frac{w_c^{(2)iso}}{w_c} = \frac{1}{k + p} \left[ \delta_{G1z}^{(obs)} - (k - p)\delta_{G2}^{(obs)} \right] \]  \quad (119)

However, Equation (119) does not allow us to determine the quadrupole coupling constant and the asymmetry to the aqueous solution. Unfortunately, \( \Omega_{F_1} \) differs from \( \Omega_{F_2} \). For the Cz convention, this difference is given by Equation (118):

From a practical point of view, in a 1-D spectrum or the \( F_2 \) dimension of a 2-D spectrum, the chemical shift of an absorption line is referenced experimentally to an external aqueous solution with \( \delta_{CS}^{(iso)} = 0 \) ppm, by definition. For both dimensions of a 2-D MQ/MAS spectrum, knowing the frequency offsets of \( w_c \) relative to the aqueous solution, \( \Omega_{F_1} \) in the \( F_1 \) dimension and \( \Omega_{F_2} \) in the \( F_2 \) dimension, allows us to express the observed chemical shifts of the center of gravity of any peak (\( \delta_{G1}^{(obs)} \) in the \( F_1 \) dimension and \( \delta_{G2}^{(obs)} \) in the \( F_2 \) dimension) relative

Figure 49 Contour plot of the (a) unsheared and (b) sheared 2-D 3Q-MAS spectra of \(^{87}\text{Rb} \ (I = \frac{3}{2}) \) in \( \text{RbNO}_3 \) powder, obtained at 98.2 MHz. The three Rb sites, Rb(1), Rb(2), and Rb(3) are observed. The axis of the \( F_1 \) dimension is labeled using the Cz convention. The \( F_2 \) dimension is the usual chemical shift axis. (Reproduced by permission of The American Physical Society from P.P. Man, Phys. Rev. B, 58, 2764–2782 (1998).)

Figure 50 The three cross-section spectra (parallel to the \( F_2 \) dimension) of the sheared 2-D 3Q-MAS spectrum of \(^{87}\text{Rb} \ (I = \frac{3}{2}) \) in \( \text{RbNO}_3 \) powder of Figure 49(b). (Reproduced by permission of The American Physical Society from P.P. Man, Phys. Rev. B, 58, 2764–2782 (1998).)
parameter \( \eta \) independently. The latter may be obtained by fitting the line shape of the cross-section (parallel to the \( F_2 \) dimension) of the peak.

Figure 49 shows the contour plots of the unsheared and sheared 2-D 3Q-MAS spectra of \(^{87}\text{Rb} \) (\( I = \frac{7}{2} \)) in \( \text{RbNO}_3 \) powder, acquired at 9.82 MHz.\(^{49} \) The \( F_1 \) axis is labeled according to the Cz convention. The three Rb sites Rb(1), Rb(2), and Rb(3) are observed. The line widths of these sheared spectra (Figure 49b) in the \( F_1 \) dimension are smaller than those in the \( F_2 \) dimension, given the high-resolution spectra along the \( F_1 \) dimension. Figure 50 presents the cross-section spectra (parallel to the \( F_2 \) dimension in Figure 49b) of the three sites.\(^{49} \) Line-shape analysis provides us with the asymmetry parameter of each rubidium site.

For convenience, Table 4 gathers the relevant relationships for the two conventions, Cz and Ck, and the two points of view (the present paper using \( w_c \) as the carrier frequency and Amoureux and colleagues using \( (k-p)w_c \) as the carrier frequency in the \( F_1 \) dimension).

4 PERSPECTIVE AND FUTURE DEVELOPMENTS

In solid-state NMR, the quadrupole coupling constant and the asymmetry parameter of half-integer quadrupole spins in a powder sample are determined by the central-transition powder pattern if the second-order quadrupole interaction is the main interaction. This powder pattern is generally observed with the one-pulse sequence; however, this is not always the case for the satellite transition. This article has presented both 1-D and 2-D methods based on Hahn echoes to determine these quadrupole parameters.

When the first-order quadrupole interaction becomes the main interaction, the central transition has a featureless line shape. The two parameters should be determined by the satellite-transition powder pattern if it is to be observed properly. Alternatively, some of the methods proposed in this article should be applied to determine these parameters from a featureless central-transition line shape, such as the two-pulse sequence with a short pulse separation.

As the strength of the Zeeman field \( B_0 \) increases year after year, the effects of the second-order quadrupole interaction, which is inversely proportional to \( B_0 \), decrease. However, the first-order quadrupole interaction, which does not depend on \( B_0 \), is likely to become the dominant interaction in the near future. If the satellite-transition powder pattern cannot be detected properly, Solomon echo sequences should be applied. Unfortunately, these echoes are not yet well characterized. Progress in understanding these echoes is required.

**LIST OF SYMBOLS**

- \( B_0 \): Zeeman field
- \( B_1 \): Radiofrequency field
- \( \delta_{\text{iso}} \): Isotropic chemical shift
- \( \delta_{\text{CS}} \): Observed chemical shift of the center of gravity of the central-transition powder pattern in the \( F_1 \) dimension
- \( \delta_{G1} \): Observed chemical shift of the center of gravity of the central-transition powder pattern in the \( F_2 \) dimension
- \( D_0 \): Recycle delay of an NMR experiment
- \( e^2 q Q / \hbar \): Quadrupole coupling constant
- \( F(t_1, \tau_2 = 0) \): Amplitude of the FID at the end of an RF pulse
- \( F_1 \): First dimension of a 2-D spectrum
- \( F_2 \): Second dimension of a 2-D spectrum
- \( \eta \): Asymmetry parameter

1 Introduction

Relaxation in NMR is a generic term for phenomena which bring the nuclear magnetization back to its equilibrium configuration after it has been perturbed. An ensemble of nuclear spins, in the presence of a static magnetic field \( B_0 \), leads to a macroscopic magnetization aligned with \( B_0 \) (this direction is usually called longitudinal, while quantities relating to a plane perpendicular to \( B_0 \) are usually called transverse). Obtaining an NMR spectrum implies taking the nuclear magnetization into a transverse configuration. This is one possible perturbation but, as will be seen later, many others exist. It can be stated at the outset, however, that longitudinal and transverse magnetizations behave independently, the former recovering to the equilibrium magnetization according to a longitudinal relaxation time \( T_1 \) (also called spin–lattice relaxation time), the latter disappearing according to a transverse relaxation time \( T_2 \) (also called spin–spin relaxation time). However, in the case of common liquids, \( T_1 \) and \( T_2 \) are usually equal and lie in the range 100 ms–30 s. Conversely, in solids, \( T_2 \) may be short – some tens of microseconds – whereas \( T_1 \) may become very long – several hundred seconds. Although the consideration of only two relaxation times is a simplistic view, it can help in understanding the basics of the complicated aspects of spin relaxation. Even if one is simply interested in the NMR spectrum itself, which, by contrast to optical spectroscopies, is known to be quantitative (since it reflects in principle the nuclear magnetization, and thus the spin concentration), one has to account for relaxation phenomena in order to use NMR as an analytical tool. Historically, as reported by Slichter in one of the best known books on NMR, the very first attempt to detect a nuclear resonance was...
hampered by the choice of a solid material whose $T_1$ was exceedingly long. In a general way and regardless of the detection mode of the NMR signal, the peak line width at half-height $\Delta \nu$ is controlled by the transverse relaxation time $T_2$ (also termed spin–spin relaxation time) according to $\Delta \nu = 1/\pi T_2$, which indicates that short $T_2$s will be responsible for a lack of resolution and may require some numerical procedures in order to separate overlapping peaks. In the early days of NMR, when spectra were obtained by continuous wave (CW) methods, it was mandatory to avoid peak saturation (so as to obtain meaningful results); saturation was controlled by the level of the applied radiofrequency (RF) field (the alternating magnetic field needed for inducing transitions) and by both $T_1$ and $T_2$. Nowadays, NMR experiments are performed by RF pulse methods which yield a so-called free induction decay (FID) or interferogram. As Fourier transformation of the FID leads to the conventional free induction decay (FID) or interferogram. As Fourier performed by RF pulse methods which yield a so-called free induction decay (FID) or interferogram. As Fourier transformation of the FID leads to the conventional spectrum, this form of spectroscopy is usually referred to as Fourier transform nuclear magnetic resonance (FTNMR). One of its major interests lies in the ability to improve efficiently the signal-to-noise ratio (S/N). Indeed, it is well known that NMR is characterized by poor sensitivity compared with most spectroscopies, and it is often necessary to repeat the experiment and to add coherently the relevant FIDs. Again, this accumulation procedure is governed by $T_1$ and some care has to be exercised in order to obtain quantitative results. Some subtler effects, such as cross-relaxation, which manifests itself through the NOE, must be considered when thoroughly analyzing an NMR spectrum. This will be discussed later in the case of multispin systems.

It must be stressed that relaxation parameters are interesting in themselves because they arise from the various interactions to which nuclear spins are subjected, the most common being the classical dipolar interaction (between the magnetic dipoles associated with nuclear spins). In order to be active, these interactions must be time dependent, e.g. via molecular motions. Therefore, relaxation parameters encompass not only structural information (through the interactions themselves) but also dynamic information (through this time modulation). This latter information can be about (i) overall motions, translational or rotational, governed essentially by the molecular volume and the viscosity of the medium in which the molecules under investigation are embedded, (ii) local motions such as internal rotations around $C=\cdot C$ bonds, or segmental motions in molecules or aggregates of appreciable size and (iii) exchange between two different molecules or between two distinct sites within the same molecule. Before considering in detail the various relaxation mechanisms, we shall first discuss experimental methods which yield the classical relaxation parameters with accuracy and reliability.

2 NUCLEAR MAGNETIC RESONANCE RELAXATION PARAMETERS AND THEIR DETERMINATION

2.1 Longitudinal Relaxation

Any experimental method aiming at the measurement of a dynamic parameter invariably starts by a perturbation which moves the system out of its equilibrium state; this is followed by an evolution period whose duration is generally denoted by $\tau$, which is such that the dynamic parameters of interest manifest themselves. The ultimate stage consists of reading the actual state of the system. Generally, this measurement is performed for different durations of the evolution period so as to evaluate the dynamic parameters properly. Regarding longitudinal relaxation, it seems obvious that the first two stages (initial perturbation and evolution) should involve only longitudinal magnetization. However, the read stage necessarily implies transverse components which are the only ones giving rise to a detectable signal. In other words, longitudinal magnetization, after having evolved, must be converted into transverse magnetization. The efficiency of the whole process will be optimal, thus providing the greatest accuracy for the determination of the considered relaxation parameter, provided that the initial perturbation is maximum. For longitudinal relaxation, this corresponds to a complete inversion by means of a $180^\circ$ (or $\pi$) RF pulse, in such a way that magnetization remains longitudinal even during the evolution period. Subsequent to the evolution period, the ongoing value of the longitudinal magnetization is read with a $90^\circ$ (or $\pi/2$) pulse which converts it into transverse magnetization, directly detectable. This is the well-known inversion–recovery experiment, which is shown schematically in Figure 1(a) and (b).

At this point, it may be instructive to recall briefly how an RF pulse works. Let us denote by $v_r$ the transmitter frequency and by $v_0$ the resonance frequency corresponding to a given peak in the NMR spectrum. It is convenient to define a frame rotating at a frequency $v_1$ around the z-axis which is the direction of the static magnetic field $B_0$. In this rotating frame, it can be shown that the RF field $B_1$ acts as if it is stationary, say along $x$. Furthermore, if the condition $(\gamma B_1/2\pi) \gg |v_1 - v_0|$ is fulfilled (the gyromagnetic ratio $\gamma$ is a constant characteristic of the considered isotope), the sole magnetic field which is able to act on nuclear magnetization is $B_1$, so that a precessional motion around $B_1$ occurs at an angular velocity $\gamma B_1$ (in the same way as transverse magnetization precesses at an angular velocity $\gamma B_0$ – the so-called Larmor frequency – in the presence of a magnetic field $B_0$). Thus starting from magnetization along $z$, an RF field applied for a time $\tau_0$, such that
Figure 1 (a) Scheme of an inversion–recovery experiment yielding the longitudinal relaxation time [inversion is achieved by means of the \((\pi)\) RF pulse, represented by a filled vertical rectangle]. FIDs (represented by a damped sine function) resulting from the \((\pi/2)\) read pulse are subjected to Fourier transformation and lead to a series of spectra corresponding to the different \(\tau\) values (evolution period). Spectra are generally displayed with a shift between two consecutive values of \(\tau\). The analysis of the amplitude evaluation of each peak from \(M_0\) to \(M_0\) provides an accurate evolution of \(T_1\). (b) The example concerns carbon-13 \(T_1\) of trans-crotonaldehyde, the values of which from left to right are 20.5, 19.8, 23.3 and 19.3 s.

\[ \gamma B_1 \tau_{90} = \pi/2, \] takes the magnetization on to the \(y\)-axis, whereas if it is applied for twice this duration it produces a complete inversion.

In a first approach, we shall limit ourselves to the hypothesis where nuclear magnetization conforms to Bloch equations. Concerning the longitudinal component, one has Equation (1):

\[ \frac{dM_z}{dt} = - \frac{M_z - M_0}{T_1} \]  

where \(M_0\) is the equilibrium magnetization. This first-order differential equation can easily be solved to yield Equation (2):

\[ M_z(\tau) = M_0 + [M_z(0) - M_0] \exp \left( -\frac{\tau}{T_1} \right) \]  

We can verify that the right-hand side of Equation (2) is equal to \(M_z(0)\) for \(\tau = 0\) and to \(M_0\) for \(\tau \to \infty\). For the ideal case of a perfect inverting \((180^\circ)\) pulse, \(M_z(0) = -M_0\) and Equation (2) reduces to Equation (3):

\[ M_z(\tau) = M_0 \left( 1 - 2 \exp \left( -\frac{\tau}{T_1} \right) \right) \]  

or, in a logarithmic form, Equation (4):

\[ \ln \left( \frac{M_0 - M_z(\tau)}{2M_0} \right) = -\frac{\tau}{T_1} \]  

This latter form is especially convenient for a quick determination of \(T_1\) which is the inverse of the slope of the linear representation of \(\ln \left( \frac{[M_0 - M_z(\tau)]/2M_0} {\tau} \right)\) vs \(\tau\) (Figure 2a and b). \(M_0\) can be measured by means of a single read-pulse or for a time \(\tau\) of the order of 5\(T_1\) (which insures a return to equilibrium of more than 99% of the magnetization).

It turns out that, in the case of an imperfect inverting pulse, the factor of 2 in Equation (3) must be substituted by an unknown factor \((K < 2)\); it is therefore recommended to turn to a nonlinear fit (based on the criterion of least-squares) (Equation 5):

\[ M_z(\tau) = M_0 \left( 1 - K \exp \left( -\frac{\tau}{T_1} \right) \right) \]  

where the three quantities \(M_0\), \(K\) and \(T_1\) have to be refined, starting for example from values deduced from

Figure 2 (a) Nonlinear fit of the data corresponding to an inversion–recovery experiment. (b) Another possible data analysis involving a semilogarithmic plot which leads directly to the longitudinal relaxation time.
Equation (4). The quality of inversion can be greatly improved by relying on the concept of composite pulses, which consists of replacing a single pulse by a cluster whose goal is to correct in a self-consistent way and, at least to first order, the various pulse imperfections. In the present context, an imperfection of the read-pulse does not matter; however, a composite pulse can be used to improve the efficiency of the initial inverting pulse, either if its duration has been misadjusted or if, because of spatial inhomogeneity of the RF field, the flip angle is not exactly 180° in all regions of the sample. Let us suppose that the inverting pulse is applied along the x-axis of the rotating frame, self-compensation can be seen to be effective if we resort to the cluster (π/2)x(π)y(π/2)x (5) where (π/2)x may be considered as a pulse of flip angle 90° − ε (whose duration is underestimated by the experimenter or due to $B_1$ inhomogeneity). We shall nevertheless assume that the (π)y pulse (acting along the y-axis of the rotating frame; this amounts to change by 90° the transmitter phase) is devoid of imperfections; this constitutes the “first-order approximation”. From the magnetization motion sketched in Figure 3(a) and (b), we can recognize that the imperfection represented by ε has been removed.

For this type of composite pulse, neither imperfections of the central (π)y pulse nor possible off-resonance effects (which occur if the condition $\gamma B_1/2\pi \gg |v_1 - v_0|$ is not fully satisfied) have been considered. It has been demonstrated empirically that both problems are attenuated by choosing a (4π/3)y pulse in place of the (π)y pulse, so that an efficient composite inverting pulse can be schematized as (π/2)x(4π/3)y(π/2)x. (6)

Finally, it must be stressed that the $T_1$ measurement, as described above, is meaningful only under the condition that the system returns to equilibrium between two experiments with different τ values, or between two consecutive scans if accumulation is necessary for improving the S/N (this requires a waiting time of the order of 5$T_1$). Variants of the inversion–recovery method have been proposed for which this latter condition is lifted, thus avoiding prohibitively long measuring times. (7) The evolution of the longitudinal magnetization is simply given by Equation (5) as in the case of an imperfect inverting pulse. $K$ depends here on the ratio $T/T_1$ (where $T$ is the repetition time) and becomes an adjustable parameter. It is even possible to go further by using the experiment sketched in Figure 4(a) and (b), denoted super fast inversion–recovery (SUFIR). (8)

The interval τ includes the acquisition of two different FIDs $S_1$ and $S_2$, which yields $T_1$ through Equation (6):

$$T_1 = \frac{\tau}{1 - \ln(S_2/S_1)}$$

The sequence is repeated $n$ times so as to reach the desired S/N.

An interesting alternative to the inversion–recovery experiment (Figure 5) is the saturation–recovery experiment, which proceeds by an initial saturation of the nuclear magnetization (total cancellation by application of long scrambling RF pulses). In that case, the initial condition is $M_z(0) = 0$ instead of $-M_0$ and the evolution is governed by Equation (7):

$$M_z(\tau) = M_0 \cdot 1 - \exp \left( -\frac{\tau}{T_1} \right)$$
An ingenious procedure was proposed by Hahn removing this contribution. To reach this goal, an experimental method must therefore be devised for achieving the desired signal-to-noise ratio.

Although the dynamic range is reduced by a factor of two, there are two distinct advantages as neither a waiting time nor an adjustment of the π pulse is needed. It should be emphasized that this method becomes valuable when magnetization cannot be inverted in the case of a very short $T_2$ (because of relaxation taking place during the pulse) or in the case of the so-called “radiation damping” (this occurs when the NMR signal is strong and induces a current in the detection coil capable of producing an alternating magnetic field which counteracts the magnetization motion, thus tending to bring it back to $+z$; this phenomenon is becoming very common with high-field sensitive spectrometers and concerns highly concentrated species, e.g. the solvent).

### 2.2 Transverse Relaxation

As stated before, the initial perturbation should be maximum with respect to the equilibrium state. Since we are dealing here with transverse magnetization, this maximum perturbation is obviously a 90° pulse. However, it can be immediately noticed that signals collected after a simple read-pulse decay exponentially according to a time constant $T_2$ which differs from the genuine $T_2$ by a contribution due to the static induction $B_0$ inhomogeneity (Equation (8)):

$$\frac{1}{T_2} = \frac{1}{T_2} + (B_0 \text{ inhomogeneity}) \quad (8)$$

Experimental methods must therefore be devised for removing this contribution. To reach this goal, an ingenious procedure was proposed by Hahn in the early 1950s, soon after the first NMR experiments. It consists of the so-called echo sequence which involves a 180° pulse in the middle of an interval of duration $2\tau$. To understand how this sequence works, let us look at the events occurring after the application of the 90° pulse. Whenever nuclear magnetization is taken to the transverse plane, it precesses at the frequency given by Equation (9):

$$\nu_0 = \frac{\gamma B_0}{2\pi} (1 - \sigma) \quad (9)$$

where $\sigma$ is the shielding coefficient, which defines the chemical shift, that is, the differentiation of various nuclei of the same isotopic species as a function of the electronic distribution by which they are surrounded (it is this feature which makes NMR such a powerful technique for identifying nuclei, e.g. protons, belonging to different chemical environments). A coil whose axis is in the transverse plane is therefore capable of detecting a signal [through an induced electromotive force (EMF)] oscillating at the frequency $\nu_0$. Now, if this signal is detected with respect to a reference frequency precisely equal to $\nu_1$ (the frequency of the rotating frame, already invoked for describing the effects of an RF pulse, corresponding to the experimental arrangement used in most spectrometers), precession actually occurs at a low frequency $|\nu_0 - \nu_1|$. Of course, the signal is attenuated by $T_2$ and one ends up with a damped sine or cosine function of the form $M_0 \cos[2\pi(\nu_0 - \nu_1)t] \exp(-t/T_2)$, assuming a (crude) exponential decay by the $B_0$ inhomogeneities, a situation generally encountered in the liquid phase.

Let us now suppose that the initial 90° RF pulse acts along the $x$-axis of the rotating frame taking the magnetization to the $y$-axis and that after a time $\tau$ we apply a 180° pulse along the $y$-axis as shown in Figure 6; this has the virtue of reversing any chemical shift effect so that after an additional time $\tau$, the magnetization again lies along the $y$-axis and a signal reappears in the form of an echo.

This pulse sequence, $(\pi/2)_x - \tau - (\pi)_y - \tau - \text{acquisition}$, is the basic Hahn sequence, which in principle yields the true $T_2$ since any precession effect is removed (in particular, precession due to $B_0$ inhomogeneities), leaving a transverse magnetization attenuated according to the transverse relaxation time. By reference to the...
Bloch equations relative to transverse magnetization (Equation 10):

$$\frac{d}{dt} M_{x,y} = - \frac{M_{x,y}}{T_2}$$

one can recognize that the Fourier transform of the half-echo leads to a signal of amplitude $M_0 \exp(-2\pi t/T_2)$. For a set of $\tau$ values, it therefore appears possible to extract an accurate value of $T_2$ for each line in the spectrum. Unfortunately, this analysis does not take into account translational diffusion phenomena, which will be now considered.

We shall assume that the $B_0$ induction is not perfectly homogeneous; for simplicity and without loss of generality, we shall make the hypothesis that it varies linearly across the whole sample in the $X$ direction of the laboratory frame so that the induction sensed by a molecule at abscissa $X$ is of the form (Equation 11):

$$B(X) = B_0 + g_0 X$$

where $g_0$ is a uniform gradient of the static field. Let us recall that such a gradient can be purposely created with the aim of producing NMR images or measuring the translational diffusion coefficient.\(^{(11)}\) This gradient can also result from a nonexistent or incomplete compensation of the genuine inhomogeneity of $B_0$ (imperfect shimming; shims are additional coils used for correcting the main field $B_0$ inhomogeneity). In any event, the precession frequency depends on the location of the considered molecule via the spatial dependence of $B_0$. We have just seen that any precession effect is refocused by an echo sequence whose goal is precisely to get rid of $B_0$ inhomogeneity. However, this feature is impaired if, during the refocusing process, molecules translate from a location $X$ to a location $X'$ for which the precession frequency is different from that at location $X$. This should produce a further signal attenuation or an additional “defocusing” which arises from self-diffusion phenomena. The latter are characterized by a self-diffusion coefficient $D$ and result in Equation (12):\(^{(11,12)}\)

$$M_{x,y}(2\tau) = M_0 \exp\left(-\frac{2\pi}{T_2}\right) \exp\left(-\frac{D\pi^2 g_0^2}{3}(2\tau^3)\right)$$

It can be recognized that the compensation of all precession effects is still accounted for in Equation (12). It can also be stressed that translational diffusion in the presence of a gradient generates a decay depending on $\tau^3$, whereas transverse relaxation produces a decay depending on $\tau$. The idea of Carr and Purcell\(^{(13)}\) was to minimize the effects of diffusion in a $T_2$ experiment. This goal is achieved by the train of 180° pulses in Figure 7 and stems from the fact that the differential equation must be solved for each interval following a 180° pulse since, at that point, the magnetization sign is suddenly modified; consequently, new boundary conditions prevail.

Returning to the analysis of the Hahn sequence and extending it to the present experiment, we obtain the amplitude of the $n$th echo (Equation 13):

$$M_{x,y}(2n\tau) = M_0 \exp\left(-\frac{2n\pi}{T_2}\right) \exp\left(-\frac{D\pi^2 g_0^2}{3}(2n\tau^3)\right)$$

We note that for an evolution whose duration is identical with that of a Hahn sequence, the argument of the exponential relevant to diffusion has been divided by $n^2$. Therefore, the remedy to make negligible translational diffusion effects consists simply in increasing $n$, which amounts to bringing the $\pi$ pulses closer to each other.

The trick introduced by Meiboom and Gill\(^{(14)}\) is to dephase all $\pi$ pulses in the Carr–Purcell train by an angle of 90° with respect to the initial $\pi/2$ pulse. As shown in Figure 8, without this phase change, imperfections of the $\pi$ pulses are cumulative, whereas with the 90° phase change, self-compensation occurs for all echoes of even number.

The CPMG experiment can be handled in two ways. First, if the spectrum involves only one resonance (or if line widths do not allow for the separation of several resonances), a single experiment can be run with acquisition of the amplitude of each echo along the pulse train (for sensitivity enhancement, accumulations can be carried out). This experiment is especially valuable for determining the relative proportions of two species which differ by their transverse relaxation time, for instance the two types of water (free and bound) in various materials (wood is a good example) or water and lipids in foodstuffs (Figure 9). For this type of measurement, a “low-resolution” spectrometer (without any shim system) is sufficient.

Second, if the spectrum involves several well-resolved resonances, one can proceed by Fourier transformation of the half-echo (possibly with signal accumulation). As many experiments as necessary are performed by varying
Figure 8 $\pi$ pulse imperfections $(\pi + \varepsilon)$ are figured out by a flip angle in excess by $\delta$. Left: errors cumulate in the simple Carr–Purcell sequence when $\pi$ pulses have the same phase as the initial $\pi/2$ pulse. Right: self-compensation at each even-numbered echo by simply shifting the phase of all $\pi$ pulses by $90^\circ$ (CPMG sequence).

Figure 9 Biexponential evolution (in fact presented as a semilogarithmic plot) of the amplitude of echoes resulting from a CPMG pulse train in the case of a sample which involves two species differing by their transverse relaxation time.

Figure 10 (a) Measurement of the transverse relaxation time in the carbon-13 doublet of formic acid (no proton decoupling) according to the sequence in Figure 7 with $\tau = 2\text{ms}$ and for successive values of $n$ (the value of $2n\tau$ is given above each spectrum). (b) Same as (a) except that proton decoupling was applied only during signal acquisition and $\tau = 5\text{ms}$.

$n$ so that the successive values of $2n\tau$ (see Equation 13) lead to $T_2$ with the required accuracy (Figure 10a and b).

In any event, a time of ca. $5T_1$ must elapse between two consecutive experiments in order to allow for a complete return of the system to thermal equilibrium. In a general way, the spectroscopist must be aware of the difficulties associated with the determination of transverse relaxation times. In homonuclear coupled spin systems, the magnetization decay is affected by ‘‘$J$-modulation’’.

It can be recalled that, in addition to chemical shifts, high-resolution NMR spectra (of liquid sample) are characterized by a fine structure arising from the so-called $J$ coupling (or indirect coupling or scalar coupling) which occurs via the spins of bonding electrons. It turns out that a $180^\circ$ pulse does not refocus $J$ coupling precession in a homonuclear system, hence the echo amplitude varies as a function of $\tau$ according to the $J$
value, making the analysis more difficult. Conversely, in the case of a heteronuclear system with observation of the rare nucleus (e.g. carbon-13), heteronuclear J coupling (e.g. with protons) is effectively refocused. On the other hand, as discussed later, a common practice in carbon-13 spectroscopy is to remove completely the effects of heteronuclear J couplings by strongly irradiating the proton transitions (proton broad-band decoupling). However, it is strongly recommended that proton decoupling be avoided during the evolution period. This is because decoupling cannot be infinitely perfect and thus induces an extra line broadening which behaves like a transverse relaxation mechanism; it also induces some heating of the solution and sample vibrations. It therefore leads to apparent irreversibility. Of course, proton decoupling can be switched on for signal acquisition in order to deal with a simpler spectrum. Rotation and vibration can be switched on for signal acquisition in order to carry out under gas flow control.

2.3 The Rotating Frame Relaxation Time $T_{1p}$

Most of the drawbacks mentioned above can be circumvented by a simple experiment, although somewhat instrumentally demanding. The sequence is depicted in Figure 11. First, a standard $(\pi/2)$ pulse flips the nuclear magnetization toward the y-axis of the rotating frame; thereafter an RF field $B_1$ is applied along that direction for a duration $\tau$. This RF field must be sufficiently strong to avoid off-resonance effects but not too strong to prevent probe deterioration. During the $\tau$ interval, magnetization should nutate around $B_1$; since both are collinear, magnetization is stationary along the y-axis of the rotating frame. It is said to be locked, hence the terminology of “spin-lock” associated with this experiment.

Any modification of the magnetization thus arises from relaxation phenomena. The transverse magnetization spin-locked along $B_1$ must end up at its thermal equilibrium value, that is, zero. The corresponding evolution is exponential with a time constant denoted by $T_{1p} (\text{relaxation time in the rotating frame})$, very close to (if not identical with) $T_2$ in practice, the signal is measured (and subsequently Fourier transformed) for a set of $\tau$ values, in successive experiments, and obeys Equation (14):

$$S(\tau) = S_0 \exp \left( \frac{-\tau}{T_{1p}} \right) \quad (14)$$

where $S_0$ is the signal amplitude immediately after the $(\pi/2)$ pulse. An immediate advantage of the method is the absence of precession during the evolution period and thus, among other things, the absence of $J$ modulation.

2.4 Cross-relaxation Rates – Nuclear Overhauser Enhancement Factors

Experimental methods outlined in the preceding section concern systems which obey Bloch equations and which consequently exhibit monoexponential evolutions according to a time constant $T_1$ for longitudinal magnetization and $T_2$ for transverse magnetization. Although in some instances Bloch equations are either strictly valid or represent a good approximation, there exist situations where biexponentiality shows up obviously and it would be a shame not to exploit this feature. Such a situation occurs whenever two spins A and X interact by a time-dependent mechanism. Such a process is termed cross-relaxation and means that any modification of the A magnetization induces a modification of X magnetization which adds up to the specific evolution of X magnetization; the symmetrical process, between X and A, of course, also holds. More formally, this coupling can be expressed via the well-known Solomon equations, which are written as Equations (15) and (16) for the two longitudinal magnetizations $I_z^A$ and $I_z^X$ (as already mentioned, any coupling between longitudinal and transverse magnetizations is impossible):

$$\frac{dI_z^A}{dt} = -R_1^A(I_z^A - I_{eq}^A) - \sigma(I_z^X - I_{eq}^X) \quad (15)$$

$$\frac{dI_z^X}{dt} = -R_1^X(I_z^X - I_{eq}^X) - \sigma(I_z^A - I_{eq}^A) \quad (16)$$

where $R_1^A$ represents the specific longitudinal relaxation rate of spin A ($R_1^A = 1/T_1^A$), $\sigma$ is the cross-relaxation rate, which reflects the coupling between the two magnetizations alluded to above, and $I_{eq}^A$ is the equilibrium magnetization. It can be seen that the Solomon equations are in fact Bloch equations to which the cross-relaxation rate $\sigma$ has been appended. $\sigma$ may have two origins:

![Figure 11 Principle of a spin-lock experiment leading to the determination of the relaxation time in the rotating frame ($T_{1p}$). (SL)$_y$ stands for the spin-lock period which corresponds to the application of an RF field along the y-axis of the rotating frame.](image-url)
1. The dipolar interaction between the two nuclei A and X, modulated by molecular motions. This contribution is very interesting with regard to the information that it contains and will be treated more explicitly in section 3.7. For the moment, it is important to know that it is proportional to \( (r_{AX})^{-6} \), where \( r_{AX} \) is the internuclear distance between A and X; this will therefore tell us if the two spins are close to each other (this is, of course, essential information in terms of molecular structure or intermolecular proximity).

2. A chemical exchange process\(^{(19)}\) such as spins move from site A to site X and conversely from site X to site A. If we define as \( \tau \) the residence time in each site (this implies identical concentrations for A and X, thus in accord precisely with the situation considered for the two spins A and X), then \( \sigma = -k = -1/\tau \). Moreover, the exchange rate \( k \) must be added to each specific rate \( R_{1}^1 \) and \( R_{2}^1 \).

We shall be concerned here with the determination of the three dynamic parameters \( R_{1}^1 \), \( R_{2}^1 \) and \( \sigma \) involved in Equations (15) and (16), deferring to section 3 their interpretation at a molecular level. A first approach consists of examining the whole evolution of \( I_{z}^{A} \) and \( I_{z}^{X} \) and, by a nonlinear analysis, extracting the three considered parameters. Because we are dealing with two simultaneous differential equations, this evolution is biexponential in nature (for both \( I_{z}^{A} \) and \( I_{z}^{X} \)). After solving the relevant equations, we obtain Equations (17) and (18):

\[
\frac{I_{z}^{A} - I_{z}^{A}(0)}{2I_{z}^{A}_{eq}} = a_{1} \exp(\lambda_{1}t) + a_{2} \exp(\lambda_{2}t) \tag{17}
\]

\[
\frac{I_{z}^{X} - I_{z}^{X}(0)}{2I_{z}^{X}_{eq}} = x_{1} \exp(\lambda_{1}t) + x_{2} \exp(\lambda_{2}t) \tag{18}
\]

where \( \lambda_{1} \) and \( \lambda_{2} \) are the roots of the characteristic equation associated with the differential Equations (17) and (18) (Equation (19)):

\[
\lambda_{1,2} = -\frac{R_{\pm}}{2} \pm \frac{X}{2} \tag{19}
\]

where \( R_{\pm} = R_{1}^1 \pm R_{2}^1 \) and \( X = \sqrt{R_{1}^1 + 4\sigma^{2}} \). The coefficients \( a_{1}, a_{2}, x_{1} \) and \( x_{2} \) depend not only on relaxation parameters but also on the initial conditions \( I_{z}^{A}(0) \) and \( I_{z}^{X}(0) \) (Equations 20 and 21):

\[
a_{1,2} = \left\{ \frac{I_{z}^{A} - I_{z}^{A}(0)}{2I_{z}^{A}_{eq}} \right\} \left( \frac{1}{2} \pm \frac{R_{\pm}}{2X} \mp \frac{I_{z}^{X} - I_{z}^{X}(0)}{2I_{z}^{X}_{eq}} \right) \times \left( \frac{I_{z}^{X}_{eq}}{I_{z}^{A}_{eq}} \right) \frac{\sigma}{X} \tag{20}
\]

The above relations are quite general in the sense they can accommodate any kind of initial conditions: non-selective inversion, selective inversion of one of the magnetizations (Figure 12) or any intermediate situation.

However, the complexity of Equations (19–23) has prompted the design of more direct methods based on the initial behavior after an appropriate perturbation. Again, we start from Equations (15) and (16) and we assume that \( t \) is short enough to ensure that a first-order expansion is adequate (Equations 22 and 23):

\[
I_{z}^{A}(t) = I_{z}^{A}(0) + t \left( \frac{dI_{z}^{A}}{dt} \right)_{t=0} \tag{22}
\]

\[
I_{z}^{X}(t) = I_{z}^{X}(0) + t \left( \frac{dI_{z}^{X}}{dt} \right)_{t=0} \tag{23}
\]

It is convenient, from a conceptual and practical point of view, to express Equations (15) and (16) in the form of the initial slopes of the reduced quantities already introduced in Equations (17) and (18) (Equations 24 and 25):

\[
S_{A} = \frac{d}{dt} \left( \frac{I_{z}^{A} - I_{z}^{A}(0)}{2I_{z}^{A}_{eq}} \right)_{t=0} = \frac{-R_{1}^{A}}{2I_{z}^{A}_{eq}} \tag{24}
\]

\[
S_{X} = \frac{d}{dt} \left( \frac{I_{z}^{X} - I_{z}^{X}(0)}{2I_{z}^{X}_{eq}} \right)_{t=0} = \frac{-\sigma}{2I_{z}^{X}_{eq}} \tag{25}
\]
These initial slopes are readily evaluated since we can always measure the signal corresponding to \( I^X_{\text{eq}} \) (or \( I^X_{\text{eq}} \)) and since the relevant instrumental factor is identical with that which prevails in the measurement of \( I^A_{\text{eq}} \) (or \( I^A_{\text{eq}} \)). Anyhow, initial conditions can be devised for determining separately one of the three relaxation parameters \( R^A_1, R^X_1 \) or \( \sigma \). The simplest experiment consists of selectively inverting one of the two magnetizations. Consider first the selective inversion of \( A \) magnetization for which the following initial conditions hold: \( I^A_{\text{eq}}(0) = -I^A_{\text{eq}} \) and \( I^X_{\text{eq}}(0) = I^X_{\text{eq}} \). This yields for the initial slopes Equations (26) and (27):

\[
S_A \ (A \ selectively \ inverted) = -R^A_1 \quad (26)
\]

\[
S_X \ (A \ selectively \ inverted) = -\sigma \quad (27)
\]

The complementary experiment (selective inversion of \( X \) magnetization) leads to Equations (28) and (29):

\[
S_A \ (X \ selectively \ inverted) = -\sigma \quad (28)
\]

\[
S_X \ (X \ selectively \ inverted) = -R^X_1 \quad (29)
\]

Another popular way of measuring the cross-relaxation rate \( \sigma \) relies upon the saturation (by continuous irradiation) of one of the two nuclei, say \( X \). Referring again to Equation (15) with \( I^X_{\text{eq}} = 0 \) (saturation of spin \( X \)) and with \( dI^A_2/dt = 0 \), which implies that a stationary state has been reached prior to the measurement (this means that the irradiation of spin \( X \) has been applied for a time sufficiently long with respect to relaxation times), we obtain a new value for the longitudinal magnetization of spin \( A \) which will be denoted \( I^A_{\text{stat}} \) (Equation 30):

\[
I^A_{\text{stat}} = I^A_{\text{eq}} \left( 1 + \frac{Y_X}{Y_A} \left( \frac{\sigma}{R^A_1} \right) \right) \quad (30)
\]

Hence, provided that \( I^A_{\text{eq}} \) is known and that \( R^A_1 \) has been determined by means of an independent experiment, \( I^A_{\text{stat}} \) provides the cross-relaxation rate \( \sigma \). This stems from the NOE (Overhauser was the first scientist to recognize that, by a related method, electron spin polarization could be transferred to nuclear spins). This effect is usually quantified by the so-called NOE factor \( \eta \) (Equation 31):

\[
\eta = \frac{I^A_{\text{stat}} - I^A_{\text{eq}}}{I^A_{\text{eq}}} = \left( \frac{Y_X}{Y_A} \right) \left( \frac{\sigma}{R^A_1} \right) \quad (31)
\]

In practice, \( I^A_{\text{stat}} \) and \( I^A_{\text{eq}} \) must be determined under identical instrumental conditions. The decoupler channel of the spectrometer is generally used for saturating the spin \( X \). Homonuclear and heteronuclear systems have to

---

Figure 13 (a) Determination of the NOE factor in the homonuclear case. The frequency of the selective irradiation is moved at a value different from \( v_X \) for the measurement of \( I^A_{\text{eq}} \). (b) Determination of the NOE factor in the heteronuclear case. The broad-band decoupler is applied a long time prior to the measurement of \( I^A_{\text{eq}} \). For the measurement of \( I^A_{\text{eq}} \) and for the sake of maintaining identical conditions, the decoupling frequency is moved far apart from its normal value and the modulation scheme is switched off (Dec. off).
be distinguished. In the former case, a weak (selective) secondary RF field centered on the X resonance is used for measuring $I_{\text{stat}}^A$, whereas $I_{\text{eq}}^A$ is obtained by the same experiment with the irradiation frequency shifted to a zone devoid of resonances; the results of these two experiments are stored in different memory blocks (Figure 13a and b). In the heteronuclear case, broad-band X decoupling (which amounts to saturating X resonances) is used to measure $I_{\text{eq}}^{AB}$. Since instrumental conditions as close as possible should be used for the measurement of $I_{\text{eq}}^{AB}$, the decoupling frequency is moved to a value significantly different (as in the homonuclear case) and the scheme is reset for signal acquisition (so as to obtain a decoupled spectrum); it should be mentioned that the NOE does not affect transverse magnetization. Again, since they concern X nuclei in their globality. In fact, this procedure.

It is perfectly clear that, although the above experiments appear especially gratifying, they should be repeated for each pair of (A,X) nuclei (with the requirement of tedious experimental adjustments since selective pulses must be employed). Heteronuclear Overhauser effect measurements constitute an exception since they concern X nuclei in their globality. In fact, the experimental procedures can be simplified and automated through the two-dimensional techniques briefly described below.

This two-dimensional method provides in a single experiment all cross-relaxation rates. The acronym NOESY (nuclear Overhauser effect spectroscopy) originates from the one-dimensional experiments described above and is mostly reserved to the study of homonuclear cross-relaxation. In a general way, the analysis of a signal $S(t_1, t_2)$ (depending on two time variables) by means of a double Fourier transformation leads to a two-dimensional map in the frequency domains $(v_1', v_2')$, whose cross-peaks (off-diagonal peaks for which $v_1' = v_1''$ and $v_2' = v_2''$) contain generally a correlation information regarding two nuclei resonating at frequencies $v_1'$ and $v_2'$. Concerning the NOESY sequence depicted in Figure 15, this correlation arises from cross-relaxation and indicates either a dipolar interaction (and thus a spatial proximity of the two considered nuclei) or chemical exchange between the two relevant sites. Let us emphasize again that the advantage of this two-dimensional technique stems from the global view of all dipolar or exchange correlations existing within the molecular system under investigation.

The preparation period allows for the return to equilibrium of nuclear magnetization. The evolution period provides a labeling according to the resonance frequency of each nucleus by repeating the experiment for incremented values of $t_1$. It will be assumed that transverse components during the mixing time $t_m$ do not affect the final result (actually this can be achieved by several means, including phase cycling procedures). This amounts to considering, prior to the mixing period, exclusively longitudinal components which are off equilibrium by an amount depending on the chemical shift of each nucleus. It is therefore conceivable that the measured signal contains effects of specific and cross-relaxations, encoded in the $t_1$ dimension according to the chemical shift. This is illustrated by Figure 16 in which the diagonal peaks depend on specific longitudinal relaxation rates whereas cross-peaks (symmetrically located with

**Figure 14** Determination of the heteronuclear Overhauser effect for the trans-crotonaldehyde molecule (experiment of Figure 13b). Carbon-13 is observed while proton is irradiated only during the signal acquisition (a) or continuously (b). The comparison of line intensities in the two spectra yields the NOE factor $\eta$ for each carbon. Note: the ppm (parts per million) scale provides the position of a given resonance with respect to the one of a reference, independently of the magnetic field value $B_0$ value. It is given by $\delta_{\text{ppm}} = (v_0 - v_{\text{ref}}) B_0/(v_{\text{measurement}}) B_0 \text{Hz}$.  

**Figure 15** Basic scheme of the NOESY sequence which provides essentially homonuclear cross-relaxation rates from a double Fourier transformation of the signal $S(t_1, t_2)$.,
respective to the diagonal) depend solely on the cross-relaxation rate between the two relevant nuclei. An example concerning biomolecular NMR is presented in Figure 17.

A similar experiment exists for measuring heteronuclear cross-relaxation rates, i.e. HOESY (heteronuclear Overhauser effect spectroscopy). Of course, it employs RF pulses which must act on both nuclei. This experiment has mostly been used for studying intermolecular proximity.

We turn now to the determination of transverse cross-relaxation rates, by contrast with the NOESY experiment which is devoted to longitudinal cross-relaxation rates. It will be shown that the latter may be positive or negative, depending on the molecular mobility, and thus may go to zero; this situation occurs at certain measuring frequencies for slowly tumbling molecules such as proteins or nucleic acids. In contrast, transverse cross-relaxation rates are always positive. In that sense, a ROESY (rotating-frame Overhauser effect spectroscopy) experiment which yields transverse cross-relaxation rates can be thought as complementary to a NOESY experiment. For theoretical reasons explained later, transverse cross-relaxation rates do not actually affect a conventional relaxation experiment using spin echoes. Rather, they become visible in a spin-lock experiment (see section 2.3). To maximize their effects, the two magnetizations of interest should be taken along the locking RF field in opposite directions. Hence, a possible design for a one-dimensional experiment is as follows: a selective pulse (i.e. where intensity has been adjusted to act only on the X nucleus) takes the X magnetization toward $-z$; it is followed by a nonselective pulse which brings both magnetizations along the spin-locking field which are then allowed to cross-talk during the mixing time $t_m$ (Figure 18).

During the mixing time $t_m$, magnetizations evolve according to the relaxation rates in the rotating frame $R^A$ and $R^X$ ($R = 1/T$, where $R$ is a relaxation rate corresponding to a relaxation time), and also according to the transverse cross-relaxation rate denoted by $\sigma_t$ (or $\sigma_z$). This is homologous to the relaxation parameters which govern the evolution of longitudinal magnetizations ($R^A$, $R^X$ and $\sigma$). We can therefore expect a similar behavior, but with relaxation rates of different values under conditions of slow molecular mobility. The two-dimensional counterpart can be deduced from the sequence in Figure 18 by substituting in $[\text{Sel}(X)(\pi/2)_X]$ a non-selective ($\pi/2$) pulse followed by an evolution period as in the NOESY sequence in Figure 15. This yields qualitatively the same type of result as a NOESY experiment: a cross-peak reveals a nonzero transverse cross-relaxation rate.
2.5 Cross-correlation Rates

$J$ splittings, when they exist, impose the definition of new spin quantities. These quantities also evolve according to relaxation phenomena and may interfere (by relaxation) with the usual magnetization components. This latter interference stems precisely from cross-correlation rates, i.e., relaxation parameters which involve two different mechanisms, e.g., dipolar interaction and the so-called chemical shift anisotropy (CSA) mechanism\(^{27,28}\) (see section 3.3). In order to illustrate what is meant by “new spin quantities”, let us consider the doublet (of splitting $J$) of one nucleus in a $J$-coupled two spin-1/2 system. Let us assume for simplicity that this spin is “on resonance” (that is, its resonance frequency $\nu_0$ is identical with the reference frequency $\nu_r$, which is also the frequency of the rotating frame), so that in the rotating frame, the resonance frequency is zero and the two lines of the doublet will just precess at frequency $\pm J/2$, respectively. As illustrated in Figure 19(a) and (b), the spin state at time $t$ can be decomposed into an “in-phase” doublet (for the components along $y$) and an “antiphase” doublet (for the components along $x$).

Using the notations of the preceding section, the in-phase doublet is obviously represented by $I^x_1$ whereas it can be shown that the antiphase doublet is represented by the product operator $2I^x_1I^x_2$. It turns out that the two quantities $I^x_1$ and $2I^x_1I^x_2$ can be coupled by a CSA–dipolar cross-correlation rate and, as a consequence, the two lines within the doublet possess different transverse relaxation rates.\(^{28,30}\) This is a simple example of spin relaxation by cross-correlation. In many other situations, cross-correlation effects can be visible.\(^{31–33}\) This will be discussed further in section 3, especially the so-called longitudinal-spin order represented by $2I^z_1I^z_2$. This latter spin state can be obtained by applying, to the previously discussed antiphase doublet ($2I^z_1I^z_2$), a $(\pi/2)_y$ selective pulse which acts exclusively on the A spin. It therefore transforms $I^z_1$ into $I^z_1$ and $2I^z_1I^z_2$ into $2I^z_1I^z_2$. On the other hand, because longitudinal magnetizations are coupled to the longitudinal order by CSA–dipolar cross-relaxation, the latter can be created in the course of a standard $T_1$ measurement and may alter the corresponding experimental results, as illustrated in Figure 20. This feature has also become especially

![Figure 19 Spin states of a doublet: (a) after a $(\pi/2)_x$ pulse and (b) some time $t$ later, and its decomposition into an in-phase and an antiphase doublet.](image)

![Figure 20 Example of the effect of cross-correlation on the longitudinal relaxation of a doublet. The differential evolution of each line within the doublet is due to the superposition of normal longitudinal magnetization and longitudinal spin order created by cross-correlation in a standard inversion–recovery experiment (the successive traces result from a read pulse, applied subsequently to the “mixing” period, which transforms the usual longitudinal magnetization into an in-phase doublet and the longitudinal spin order into an antiphase doublet).](image)
apparent in measurements performed on proteins with spectrometers equipped with high magnetic field $B_0$.\(^{(34)}\)

### 3 RELAXATION MECHANISMS

The only way to perturb a spin system from its equilibrium configuration or to take it back to its equilibrium state is to induce transitions. This, of course, can be done by application of an RF field or through magnetic fields governing relaxation phenomena. Consider a spin-1/2 system, that is, a system involving only two energy levels. As already stated, for inducing a transition between these two states, the experimenter can apply an RF field at the Larmor frequency $\nu_0$ such that we have Equation (32) (see Figure 21):

$$h\nu_0 = \Delta E = \frac{\gamma h B_0}{2\pi}$$

where $\nu_0 = \gamma B_0/2\pi$ and the shielding coefficient has been omitted.

On the other hand, within a sample, an elementary nuclear magnetic moment $\mu$ is subjected to a local magnetic field $b(t)$ originating from the various interactions to which this magnetic moment is subjected. Owing to molecular motions, these local fields are time dependent and consequently may be able to induce transitions. They must, however, mimic the action of an RF field and therefore fulfill the following conditions: (i) present some degree of coherence and (ii) be active at the frequency of the considered transition.

#### 3.1 Interaction with Local Fluctuating Magnetic Fields

$b(t)$ is, for instance, the magnetic field created by another spin (nuclear spin or the spin of an unpaired electron); in that case, it is proportional to $1/r^2$ (where $r$ is the distance between the two spins). Its time dependence arises from the orientation of $r$ and/or from the distance fluctuation. However, with the approach considered in this section, we disregard the origin of $b(t)$ and we rest only on its general properties which arise from the random nature of molecular motions:

![Figure 21](image)

**Figure 21** The two energy levels of a spin-1/2 system corresponding to the spin states $|\alpha\rangle$ and $|\beta\rangle$. The two possible transitions, represented by up and down arrows, must satisfy the Bohr relation $h\nu_0 = \Delta E$, where $\nu_0$ is the resonance frequency.

1. the three components of a local magnetic field are not correlated (Equation 33):

$$\overline{b_x(t)b_x(t)} = \overline{b_y(t)b_y(t)} = \overline{b_z(t)b_z(t)} = 0 \quad (33)$$

(the bar represents an ensemble average);

2. the mean value of each component is zero (Equation 34):

$$\overline{b_x(t)} = \overline{b_y(t)} = \overline{b_z(t)} = 0 \quad (34)$$

3. the mean values of their squares are identical (Equation 35):

$$\overline{b_x^2(t)} = \overline{b_y^2(t)} = \overline{b_z^2(t)} = b^2 \quad (35)$$

(in an isotropic medium).

To understand the last two points, one can think of a quantity whose modulus is nonzero but which can take opposite values with the same probability.

The coherence of a random field can be evaluated by its correlation function, e.g. Equation (36):

$$\overline{b_x(t)b_x(0)} \neq 0 \quad (36)$$

which reflects its memory properties. Indeed, if the two quantities are totally uncorrelated (independent), one has Equation (37):

$$\overline{b_x(t)b_x(0)} = \overline{b_x(t)}\overline{b_x(0)} = 0 \quad (37)$$

Conversely, an RF field is totally correlated because it is represented by a sine (or cosine) function and, as a consequence, its value at any time $t$ can be predicted from its value at time zero. The efficiency of a random field at a given frequency $\nu = \nu / (2\pi)$ can be appreciated by the Fourier transform of the above correlation function (Equation 38):

$$\rho(\nu) = \frac{\infty}{0} \overline{b_x(t)b_x(0)} \exp(-i\nu t) \, dt \quad (38)$$

These quantities are called spectral densities and are involved in any relaxation parameter. Very often $\overline{b_x(t)b_x(0)}$ can be written as $\frac{\nu^2}{2}\exp(-t/\tau_c)$, where $\tau_c$ is a correlation time associated with molecular reorientation (it can be thought as the time required for rotation by 1 rad; in liquids $\tau_c$ lies between $10^{-9}$ and $10^{-12}$ s). The above Fourier transform leads to a Lorentzian function of the type $\tau_c/1 + w^2\tau_c^2$. When the condition $w^2\tau_c^2 \ll 1$ is fulfilled (and this is the case for fast motions since the NMR measurement frequency is $<10^9$ Hz), the spectral density becomes independent of frequency. In such a case, one says that “extreme narrowing” conditions prevail.

We now intend to derive the Bloch equations in order to express $T_1$ and $T_2$ according to spectral densities at appropriate frequencies. The starting point
is the evolution equation of an elementary magnetic moment $\vec{\mu}$ subjected to a random field $\vec{b}$ (Equation 39):

$$\frac{d}{dt}\vec{\mu} = \gamma \vec{\mu} \wedge \vec{b}$$  \hspace{1cm} (39)

One has, e.g. for $\mu_z$ (Equation 40):

$$\frac{d}{dt}\mu_z = \gamma (\mu_z b_y^* - \mu_y b_x^*) \hspace{1cm} (40)$$

The prime indicates that one has switched to the so-called rotating frame in order to remove any precession effect at the angular velocity $\omega_0 = 2\pi v_0$, $v_0$ being the resonance frequency (Equations 41 and 42):

$$b_x' = b_x \cos(\omega_0 t) - b_y \sin(\omega_0 t) \hspace{1cm} (41)$$  
$$b_y' = b_x \sin(\omega_0 t) + b_y \cos(\omega_0 t) \hspace{1cm} (42)$$

One can always write (Equation 43):

$$\mu_z(t) = \mu_z(0) + \int_0^t \frac{d\mu_z}{dr} dr'$$ \hspace{1cm} (43)

and proceed by time-dependent perturbation methods\(^{35}\) (the relevant calculations will be avoided). It can be remembered that the quantity of interest is the $z$ component of nuclear magnetization (Equation 44):

$$M_z(t) = \mu_z(t) \hspace{1cm} (44)$$

After some algebra (and some physico-mathematical tricks), one arrives at Equation (45):

$$\frac{d}{dt}M_z = -(M_z - M_0)\gamma^2 \int_0^\infty \frac{b_x(t)b_x(0) + b_y(t)b_y(0)}{2} e^{-iw_0 t} dt$$ \hspace{1cm} (45)

where $M_0$ is the equilibrium magnetization. This leads to the familiar Bloch equation pertaining to longitudinal magnetization (Equation 46):

$$\frac{d}{dt}M_z = -\left(\frac{1}{T_2}\right) (M_z - M_0) \hspace{1cm} (46)$$

with (Equation 47) (rf standing for “random fields”):

$$\left(\frac{1}{T_2}\right)_{rf} = (R_2)_{rf} = \gamma^2 \int_0^\infty \frac{\tau}{\tau_f + \tau} dt$$ \hspace{1cm} (47)

where $R_1$ is the inverse of the longitudinal relaxation time and is called the longitudinal relaxation rate. Similar calculations applied to transverse components lead to Equation (48):

$$\frac{d}{dt}M_{x,y} = -\left(\frac{1}{T_2}\right)_{rf} M_{x,y} \hspace{1cm} (48)$$

with (Equation 49):

$$\left(\frac{1}{T_2}\right)_{rf} = (R_2)_{rf} = \gamma^2 \int_0^\infty \frac{\tau}{\tau_f + \tau} dt \hspace{1cm} (49)$$

Notice the presence in $R_2$ of a spectral density at zero frequency arising from $\int_0^\infty b_x(t)b_x(0)dt$ (which evidently does not require a switch to the rotating frame).

Likewise (Equation 50):

$$\left(\frac{1}{T_1}\right)_{rf} = \gamma^2 \int_0^\infty \frac{\tau}{\tau_f + \tau} dt \hspace{1cm} (50)$$

with $w_1 = \gamma B_1$ ($B_1$ = spin-lock field).

It can be interesting, within this simple model, to visualize the evolution of $T_1$ and $T_2$ as a function of $v_0$ and of $\tau_c$. For this goal we shall assume the simplest form for $\tau_f(w_0)$, that is (Equation 51):  

$$\tau_f(w_0) \propto \frac{\tau_c}{1 + w_0^2 \tau_c^2} \hspace{1cm} (51)$$

This yields the curves for $T_1$ and $T_2$ given in Figures 22 and 23.

---

**Figure 22** Evolution of the longitudinal and transverse relaxation times, $T_1$ and $T_2$, respectively, assuming that the considered spin is subjected to random fields whose correlation function is proportional to $e^{-t/\tau}$, $\tau_c$ being the correlation time with the magnitude field $B_0$ (or, equivalently, with the measurement of resonance frequency, $v_0$). For $\tau_c = 1 \text{ ps}$, extreme narrowing conditions are seen to be fulfilled.
3.2 Overview of the Various Interactions Responsible for Relaxation Phenomena

3.2.1 Dipolar Interaction

This mechanism concerns the direct interaction between the magnetic moments associated with nuclear or electron spins (see Figure 24). In the case of an unpaired electron, this mechanism is called pseudo-contact interaction.

The time modulation may have two origins: (i) reorientation of $r$ due to molecular tumbling (intramolecular) or (ii) modulation of the distance $r$ (intermolecular).

3.2.2 Chemical Shift Anisotropy

This originates from the tensorial nature of the shielding effect (responsible for chemical shift phenomena); its time dependence is due to the reorientation (with respect to the laboratory frame when the $Z$-axis coincides with $B_0$ of the tensor principal axes under molecular tumbling and is intramolecular by nature (Figure 25). These principal axes constitute a unique molecular frame depending on the electronic distribution and the considered interaction.

3.2.3 Quadrupolar Mechanism

The interaction between the quadrupole moment of nucleus of spin $>1/2$ with the electric field gradient (EFG) is tensorial and the time modulation arises again from the orientation of the PAS with respect to the $B_0$ direction, as for the CSA mechanism (Figure 25).

3.2.4 Spin Rotation

This is associated with the coupling between the spin angular momentum and the angular momentum describing the rotation of the electronic cloud. It is effective for small molecule or rotating methyl groups. Contrary to the other mechanisms, it produces a decrease in relaxation times when the temperature increases.

3.2.5 Scalar Relaxation of the First Kind

This concerns exchange phenomena and will not be considered further.

3.2.6 Scalar Relaxation of the Second Kind

This mechanism occurs when a slowly relaxing spin interacts with a fast relaxing spin (e.g. quadrupolar nucleus; unpaired electron, in that case it will be termed “contact interaction”) to which it is $J$ coupled (hyperfine coupling in the case of an unpaired electron).

3.3 Relaxation by Chemical Shift Anisotropy

Let $B_0$ be the static magnetic field of the NMR experiment. The actual field sensed by the nucleus has for components (in the laboratory frame $X, Y, Z$) (Equations 52–54):

$$b_X = \sigma_{XZ}B_0 \quad (52)$$
$$b_Y = \sigma_{YZ}B_0 \quad (53)$$
$$b_Z = (1 - \sigma_{ZZ})B_0 \quad (54)$$
where $\sigma_{XZ}$, $\sigma_{YZ}$ and $\sigma_{ZZ}$ are elements of the shielding tensor expressed in the laboratory frame. It can be recalled that these quantities are very small (of the order of $10^{-6}$) and reflect the actual field sensed by the nucleus under investigation. Of course, $b_Z$ remains the major overwhelming component. As these elements fluctuate in time owing to molecular tumbling, the local field (random field) does so also. This mechanism is therefore active as far as spin relaxation is concerned. However, rather than dealing with spectral densities involving random fields, it would be more informative to deal with spectral densities involving elements of the shielding tensor. One therefore defines a new spectral density (Equation 55):

$$
csa(w) = \frac{1}{0} \frac{\sigma_{ZZ}(t)\sigma_{ZZ}(0) \exp(-iwt) dt}{\sigma_{ZZ}(t)\sigma_{ZZ}(0) \exp(-iwt) dt} (55)
$$

It can be shown that (in an isotropic medium) (Equation 56):

$$
\frac{1}{0} \frac{\sigma_{ZZ}(t)\sigma_{ZZ}(0) \exp(-iwt) dt}{\sigma_{ZZ}(t)\sigma_{ZZ}(0) \exp(-iwt) dt} = \frac{1}{2} \ csa(w) (56)
$$

Now, from Equation (45), we can remember that (Equation 57):

$$
\frac{1}{T_1} = \frac{\gamma^2}{0} \frac{(b_X(t)b_X(0) + b_Y(t)b_Y(0)) e^{-iwt} dt}{b_X(t)b_X(0) + b_Y(t)b_Y(0)} (57)
$$

which leads to Equation (58):

$$(R_1)^{CSA}_{CSA} = \frac{1}{2} \gamma^2 B_0^2 csa(w_0) (58)
$$

Likewise (Equation 59):

$$(R_2)^{CSA}_{CSA} = \frac{1}{2} \gamma^2 B_0^2 csa(w_0) + csa(0) (59)
$$

As immediate consequences, we can state that (i) $R_1$ and $R_2$ vary according to the square of the static magnetic field, and this contribution can therefore be sorted out by experiments performed at different magnetic fields, and (ii) under extreme narrowing conditions (Equation 60):

$$(R_2)^{CSA}_{CSA} = \frac{7}{6} (R_1)^{CSA}_{CSA} (60)
$$

In order to extract still more information from the CSA contribution to relaxation times, the next step is to switch to a molecular frame $(x,y,z)$ where the shielding tensor is diagonal $(x,y,z$ is called the PAS). The relevant calculations involve irreducible tensors, Wigner matrices and other spherical harmonics. They yield for an isotropic reorientation (the molecule being supposed to behave as a sphere) (Equations 61 and 62): 

$$(R_1)^{CSA}_{CSA} = \frac{1}{15} (\gamma B_0)^2 (\Delta \sigma)^2 \left(1 + \eta_{CSA}^2 \right) J(w_0) (61)
$$

$$(R_2)^{CSA}_{CSA} = \frac{1}{15} \frac{(\gamma B_0)^2 (\Delta \sigma)^2 \left(1 + \eta_{CSA}^2 \right)}{2} \times \frac{2J(0)}{3} + \frac{J(w_0)}{} (62)
$$

where $\Delta \sigma = (\sigma_{zz} - (\sigma_{xx} + \sigma_{yy})/2$ is the shielding anisotropy, $\eta_{CSA} = (3/2)(\sigma_{xx} - \sigma_{yy})/\Delta \sigma$ is the asymmetry parameter and the reduced spectral density, $J(w)$, discussed in section 3.5, contains only dynamical information. In the case of an axially symmetry shielding tensor and for any kind of molecular tumbling, one can use the above equations with $\eta_{CSA} = 0$ and evaluate the reduced spectral densities according to the actual molecular motions.

### 3.4 Scalar Relaxation of the Second Kind

The usual example is a spin-1/2 nucleus (A), $J$ coupled to a fast relaxing quadrupolar nucleus (X) with relaxation times $T_{2X}$ and $T_{2X}^X$ (and spin number $I_X$). The relevant interaction is of the form in Equation (63) ($J_{AX}$ in hertz):

$$J_{AX}(I_X^X I_X^X + I_X^Y I_X^Y + I_X^Z I_X^Z) (63)$$

Because of fast X relaxation (which usually prevents the observation of $J$ splittings; see section 4.4), $J_{AX}I_X^X$ can be considered as a random field $y_b$, acting on $A$. Consequently, correlation functions of the type $I_X^X(t) I_X^X(0)$ have to be evaluated (in this case $T_{2X}^X$ plays the role of a correlation time). After some calculations, one arrives at Equations (64) and (65):

$$(R_1)^{CSA}_{SC} = \frac{8\pi^2 J_{AX}^2}{3} I_X(I_X + 1) \frac{T_{2X}^X}{1 + (w_X - w_A)^2(T_{2X}^X)^2} (64)$$

$$(R_2)^{CSA}_{SC} = \frac{4\pi^2 J_{AX}^2}{3} I_X(I_X + 1) \times \frac{T_{2X}^X}{1 + (w_X - w_A)^2(T_{2X}^X)^2} + T_{1X}^X (65)$$

It can be seen that (i) owing to the importance of $(w_X - w_A)^2(T_{2X}^X)^2$, $(R_1)^{CSA}_{SC}$ is generally negligible unless $w_X$ is close to $w_A$ (this may no longer be true if X is an unpaired electron), and (ii) for the same reason, $(R_2)^{CSA}_{SC} \approx 4\pi^2 J_{AX}^2 I_X(I_X + 1)/3$ and is able to provide the value of the $J_{AX}$ coupling constant.

This mechanism is also related to the “contact interaction” between an unpaired electron and a nuclear spin (in that case the hyperfine coupling replaces the $J$ coupling).
3.5 Reduced Spectral Densities

In order to handle the correlation function involving the component of a cartesian tensor expressed in the laboratory frame, e.g. $σ_{zz}(t)σ_{zz}(0)$, it is recommended to switch to a molecular frame. The objective of such an operation is to separate structural properties (molecular frame) from dynamic properties (contained in the function relating the laboratory frame to the molecular frame). This task is relatively easy when the considered interaction can be represented in the molecular frame by a unique direction (sometimes called the relaxation vector, e.g. the vector joining the two magnetic moments when dealing with dipolar interactions). This is the case (i) when molecular reorientation is isotropic (the considered molecule can be considered as a sphere) and all directions are equivalent, or (ii) if the tensor (expressed in the molecular frame) is axially symmetric. The relaxation vector corresponds in that case to the symmetry axis.

In such a situation, the spectral densities encountered so far and denoted are proportional to a reduced spectral density denoted by $\tilde{J}(w)$ (Equation 66):

$$\tilde{J}(w) = 4\pi \int_{-\infty}^{+\infty} Y_2^0[\Theta(t)]Y_2^0[\Theta(0)]\exp(-iw\tau_\Theta)\,dt \quad (66)$$

where $\Theta$ is the angle between the relaxation vector and the preferential direction of the magnetic resonance experiment (i.e. the direction of $B_0$) and where the spherical harmonics $Y_2^0$ has the form (Equation 67):

$$Y_2^0(\Theta) = \sqrt{\frac{5}{16\pi}} (3\cos^2\Theta - 1) \quad (67)$$

In the case of an isotropic reorientation described by a simple correlation time $\tau_c$, one has (Equation 68):

$$\tilde{J}(w) = \frac{2\tau_c}{1 + w^2\tau_c^2} \quad (68)$$

Conversely, if the reorientation of a rigid molecule is anisotropic, three correlation times, associated with the PAS of the rotation diffusion tensor, are required. They lead to complicated (unwieldy) equations,$^{(35)}$

In many situations (e.g. in large molecules), molecular reorientation can be viewed as the combination of an overall (slow) isotropic molecular reorientation (represented by a correlation time $\tau_i$) and (fast) internal motions (represented by a correlation time $\tau_f$) and it is recommended to turn to the widely used model-free approach,$^{(36)}$ equivalent to the two-step model$^{(37)}$ (Equation 69):

$$\tilde{J}(w) = \frac{2\tau_f}{1 + w^2\tau_f^2}(1 - S^2) + S^2 \frac{2\tau_i}{1 + w^2\tau_i^2} \quad (69)$$

Figure 26 Definition of the angle $\theta$ involved in the calculation of the order parameter. $D$ is a local director.

$S$ is a generalized order parameter (similar to the quantity describing partial orientation in liquid crystals) which quantifies the motional restriction of the relaxation vector with respect to a local director $D$ (e.g. the molecular long axis in the case of an alkyl chain). The order parameter is calculated as follows (Equation 70):

$$S = \frac{1}{2}(3\cos^2\theta - 1) \quad (70)$$

The brackets denote an average (see Figure 26 for the definition of $\theta$). As a consequence, $-0.5 \leq S \leq 1$ and in the absence of any order $S = 0$ since $(\cos^2\theta) = 1/3$.

Measurements at different magnetic fields (different frequencies) yield in principle all dynamic parameters: $\tau_f, S$ and $\tau_i$ (see Figure 27).

It can be noted that (i) $\tilde{J}(0)$ (involved in $R_c$) is essentially equal to $2S^2\tau_s$ and (ii) at high frequencies, $\tilde{J}(w_0/(2\pi))$ is dominated by fast motions. Slow motions are probed by measurements performed at (very) low fields according to a technique known as relaxometry.$^{(38)}$

Figure 27 Evolution of the reduced spectral density as a function of the measurement frequency (or equivalently as a function of the magnetic field) when the model-free approach is invoked.
3.6 Relaxation in Coupled Spin Systems – Redfield Equations

If the spin system cannot be described by two states (e.g. $|\alpha\rangle$ and $|\beta\rangle$, as is the case for a single spin-1/2 system), macroscopic magnetization components are no longer sufficient (i.e. the classical description of spin dynamics). One must therefore turn to quantum mechanics. This is true for a system involving two spins-1/2 which possesses four eigenstates (for a weakly coupled spin system they are described by $|\alpha, \alpha\rangle$, $|\alpha, \beta\rangle$, $|\beta, \alpha\rangle$ and $|\beta, \beta\rangle$), and for a quadrupolar nucleus (three states for a spin-1, four states for a spin-3/2 and so on). The appropriate tool is the density matrix, which combines the description of the quantum system along with the statistical average. The details of this approach, which require a considerable amount of mathematics, will be avoided. Only the essential features and properties of the density matrix will be outlined. Let $|\alpha\rangle$ and $|\alpha'\rangle$ be two spin states. The element $\sigma_{\alpha\alpha'}$ of the density matrix is defined according to Equation (71):

$$\sigma_{\alpha\alpha'} = \bar{c}_\alpha \bar{c}_{\alpha'}$$  \hspace{1cm} (71)

where $c_\alpha$ and $c_{\alpha'}$ are the probability of finding a spin system in the states $|\alpha\rangle$ and $|\alpha'\rangle$, respectively. As usual, the bar denotes an ensemble average, i.e. an average over all systems constituting the sample. It follows that the diagonal element $\sigma_{\alpha\alpha}$ corresponds to the population of the relevant energy level, $P_\alpha$ (Equation 72):

$$P_\alpha = \sigma_{\alpha\alpha}$$  \hspace{1cm} (72)

which, at equilibrium, is proportional to $\exp(-E_\alpha/kT)$. Diagonal elements are therefore related to longitudinal magnetization. The off-diagonal element $\sigma_{\alpha\alpha'}$ corresponds to a coherence. At equilibrium, there is no phase relationship between $|\alpha\rangle$ and $|\alpha'\rangle$, meaning that $\sigma_{\alpha\alpha'}$ is zero. A nonzero value of $\sigma_{\alpha\alpha'}$ indicates some degree of coherence between $|\alpha\rangle$ and $|\alpha'\rangle$, and thus the presence of some transverse magnetization associated with the transition $|\alpha\rangle \rightarrow |\alpha'\rangle$ (there is, of course, full coherence if $|\alpha\rangle = |\alpha'\rangle$). The density matrix evolves according to Redfield equations (39) (Equation 73):

$$\frac{d}{dt} \sigma_{\alpha\alpha'} = i(w_{\alpha'} - w_\alpha)\sigma_{\alpha\alpha'} + \sum_{b,b'} R_{\alpha\alpha'bb'}\sigma_{bb'}$$  \hspace{1cm} (73)

The first term, depending on $(w_{\alpha'} - w_\alpha)$, is related to precession $(w_{\alpha'}$ and $w_\alpha$ represent the energy values of eigenstates $|\alpha\rangle$ and $|\alpha'\rangle$ expressed in radians per second) and the second term is related to relaxation ($R$ = relaxation matrix). It is nonzero only if (Equation 74):

$$|w_{\alpha'} - w_\alpha| \approx |w_{\alpha'} - w_\beta|$$  \hspace{1cm} (74)

Some immediate consequences of the Redfield equations can be formulated as follows:

Longitudinal relaxation (Equation 75):

$$\frac{d}{dt} \sigma_{\alpha\alpha} = \sum_b R_{\alpha\alpha bb}\sigma_{bb}$$  \hspace{1cm} (75)

which can be recast as Equation (76):

$$\frac{d}{dt} P_\alpha = \sum_b W_{ab} P_b$$  \hspace{1cm} (76)

with $W_{ab} = R_{\alpha\alpha bb}$, which is the probability of a transition induced by relaxation. A diagonal element is coupled to other diagonal elements. Therefore, longitudinal magnetization and transverse magnetization are not connected by relaxation phenomena.

Transverse relaxation: consider an isolated line in the NMR spectrum, corresponding to the transition $|\alpha\rangle \rightarrow |\alpha'\rangle$. The relevant element of the density matrix evolves according to Equation (77):

$$\frac{d}{dt} \sigma_{\alpha\alpha'} = [i(w_{\alpha'} - w_\alpha) + R_{\alpha\alpha'bb'}]\sigma_{bb'}$$  \hspace{1cm} (77)

which would correspond (if $B_0$ inhomogeneity is negligible) to the line width at half-height equal to $R_{\alpha\alpha'/\pi}$.

3.7 Longitudinal Relaxation in a Weakly Coupled Two-spin-1/2 System

From the diagram displayed in Figure 28, it is apparent that (Equations 78 and 79):

$$\langle I_\zeta^A \rangle \propto (P_1 - P_3) + (P_2 - P_4)$$  \hspace{1cm} (78)

$$\langle I_\zeta^X \rangle \propto (P_1 - P_2) + (P_3 - P_4)$$  \hspace{1cm} (79)

$d(I_\zeta^A)/dt$ and $d(I_\zeta^X)/dt$ will therefore involve all transition probabilities including zero-, one- and double-quantum transitions, at the respective frequencies $(w_A - w_X)$, $w_A$, $w_X$ and $(w_A + w_X)$. It can be recalled that one-quantum transitions are blocked (if $B_0$ inhomogeneity is negligible) to the line width at half-height equal to $R_{\alpha\alpha'/\pi}$.

![Figure 28](image-url)

**Figure 28** Energy level of a two-spin system. Full arrows, normally observed one-quantum (1Q) transitions; dashed arrows, zero-quantum (ZQ) and double-quantum (DQ) transitions.
transitions are those normally observed, which involve, for a given spin, the change of \( \alpha \) into \( \beta \) (or \( \beta \) into \( \alpha \)). Double-quantum transitions involve the same change for both spins, and zero-quantum transitions are such that for one spin \( \alpha \) is changed into \( \beta \) and for the other spin \( \beta \) is changed into \( \alpha \).

Complete calculations lead to the Solomon equations given in section 2.4 (Equations 80 and 81):

\[
\frac{d}{dt}(I_{\alpha}^A) = -R_{1}^A(I_{\alpha}^A - I_{\text{eq}}^A) - \sigma(I_{\alpha}^X - I_{\text{eq}}^X) \tag{80}
\]
\[
\frac{d}{dt}(I_{\beta}^X) = -R_{1}^X(I_{\beta}^X - I_{\text{eq}}^X) - \sigma(I_{\beta}^A - I_{\text{eq}}^A) \tag{81}
\]

where \( R_{1}^A \) and \( R_{1}^X \) are specific relaxation rates depending in an additive way on the AX dipolar interaction, \( (R_{1}^A)_{d} \) or \( (R_{1}^X)_{d} \), and on other possible mechanisms. As already discussed in section 2.4, \( \sigma \) is a coupling term between A and X longitudinal magnetizations, also called cross-relaxation rate, depending solely on the AX dipolar interaction. From the above theory, relaxation parameters can be expressed as Equation (82):

\[
(R_{1}^A)_{d} = K_{AX}[6\tilde{J}(w_{A} + w_{X}) + 3\tilde{J}(w_{A})] \uparrow \text{DQ} \uparrow \text{1Q} \\
+ \tilde{J}(w_{A} - w_{X}) + (R_{1}^A)_{\text{others}} \uparrow \text{ZQ} \tag{82}
\]

and (Equation 83):

\[
\sigma = K_{AX}[6\tilde{J}(w_{A} + w_{X}) - \tilde{J}(w_{A} - w_{X})] \uparrow \text{DQ} \uparrow \text{ZQ} \tag{83}
\]

where DQ, 1Q, ZQ stand for double-, one- and zero-quantum coherences, respectively, and (Equation 84):

\[
K_{AX} = \frac{\mu_{0}^{2}}{20 \pi} \frac{\gamma_{A}^{2} \gamma_{X}^{2} \hbar}{r_{AX}^{2}} \tag{84}
\]

Conversely, the transverse relaxation rate originating from dipolar contribution is expressed as Equation (85), given here for the sake of comparison:

\[
(R_{2}^A)_{d} = K_{AX} \frac{3\tilde{J}(w_{A} + w_{X}) + 3\tilde{J}(w_{A})}{2} + \tilde{J}(w_{A} - w_{X}) \frac{3\tilde{J}(0)}{2} + 2\tilde{J}(0) \tag{85}
\]

From the Solomon equations, we can immediately derive two important properties:

1. In a general way, longitudinal magnetization exhibits a biexponential behavior:

(a) unless X is continuously irradiated, in which case (Equation 86):

\[
\frac{d}{dt}(I_{\alpha}^A) = -R_{1}^A(I_{\alpha}^A - I_{\text{eq}}^A) \tag{86}
\]

with (Equation 87):

\[
I_{\text{stat}}^A = I_{\text{eq}}^A \left(1 + \frac{\sigma}{R_{1}^A} \frac{\gamma_{X}}{\gamma_{A}} \right) \tag{87}
\]

(b) or unless A and X constitute a homonuclear system \((w_{A} = w_{X} = w_{0})\), subjected to nonselective pulses (like spins), in which case \( R_{1}^A \) and \( \sigma \) have to be added, leading to a monoexponential evolution with (Equation 88):

\[
(R_{1}^{\text{like}})_{d} = K[12\tilde{J}(2w_{0}) + 3\tilde{J}(w_{0})] + (R_{1})_{\text{others}} \tag{88}
\]

2. If extreme narrowing conditions prevail (Equations 89–91):

\[
(R_{1}^A)_{d} = K_{AX}(20\tau_{C}) \tag{89}
\]

\[
\sigma = K_{AX}(10\tau_{C}) = \frac{(R_{1}^A)_{d}}{2} \tag{90}
\]

\[
(R_{1}^{\text{like}})_{d} = K(30\tau_{C}) = \frac{3(R_{1}^A)_{d}}{2} \left(\frac{3}{2} \text{ effect} \right) \tag{91}
\]

Under these conditions, it can be seen that \((R_{1}^A)_{d} = (R_{2}^A)_{d}\).

3.8 The Nuclear Overhauser Effect

In a two-spin system involving dipolar interaction, the quantity of interest is obviously the cross-relaxation rate because of its unique dependence on the internuclear distance and on the reorientation of the internuclear vector. Referring to Equation (83), we can always write (Equation 92):

\[
\sigma \propto \frac{1}{\rho^2} \times (\tau_{C}^{\text{eff}}) \uparrow \text{geometry} \uparrow \text{dynamic properties} \tag{92}
\]

If \( \tau_{C}^{\text{eff}} \) can be estimated from another measurement, it yields the internuclear distance \( r \) whereas it provides dynamic information if \( r \) is known. The most popular way of measuring \( \sigma \) is the so-called NOE factor (see section 2.4) (Equation 93):

\[
\eta = \frac{I_{\text{stat}}^A - I_{\text{eq}}^A}{I_{\text{eq}}^A} = \frac{\gamma_{X} \sigma}{\gamma_{A} R_{1}^A} \tag{93}
\]
$R_1^A$ being determined from an independent measurement. If $R_1^A$ is dominated by the dipolar mechanism and under extreme narrowing conditions (Equation 94):

$$\eta_{\text{max}} = \frac{\gamma_A}{\gamma_c} = 2 \text{ for the } ^{13}\text{C}-^1\text{H system}$$

$$= 0.5 \text{ for a homonuclear case}$$

Because of the difference in resonance frequencies, transverse magnetizations are not affected by cross-relaxation (see Equation 77). In the presence of a spin-lock field, this difference in resonance frequencies is removed and cross-relaxation reappears. This is the basis of the homonuclear ROESY experiment, which depends on cross-relaxation rates of the form in Equation (95):

$$\sigma_p(\sigma_{\perp}) = K_{AX}[3J(w_0) + 2J(w_1)]$$

with $w_1 = \gamma B_1$ much smaller than $w_0 = \gamma B_0$, while it can be recalled that the conventional cross-relaxation rate for a homonuclear system can be expressed as Equation (96):

$$\sigma = (\sigma_{\parallel}) = K_{AX}[6J(2w_0) - J(0)]$$

This involves a term affected by the minus sign, hence $\sigma_{\parallel}$ can go to zero. As a consequence, the cross-relaxation rate $\sigma_{\parallel}$ is prone to yield strong (negative) responses whenever $J(0)$ is overwhelming in the case of slow motions. In unfavorable circumstances (correlation time vs measurement frequency), $6J(2w_0)$ may become comparable to $J(0)$ and the responses will be negligibly small. In that case $\sigma_L$ should be preferred (Figure 29).

### 3.9 The Chemical Shift Anisotropy–Dipolar Interference Term

So far, for describing longitudinal relaxation in a two spin-1/2 system, two quantities have been invoked, namely $\langle I_x^A \rangle$ and $\langle I_x^X \rangle$. As this system involves four energy levels, four quantities would normally be required. A third (trivial) quantity is the identity. The fourth quantity is the so-called longitudinal order represented by the “operator product” $2I_z^A I_z^X$, already introduced in section 2.5. Longitudinal order is zero at thermal equilibrium and can be created through cross-correlation between the dipolar interaction and the CSA mechanism (interference term) in such a way that the Solomon equations must be extended to

$$(\text{Equations 97–99}):$$

$$\frac{d}{dt}\langle I_x^A \rangle = -R_1^A(\langle I_x^A \rangle - I_x^{\text{eq}}) - \sigma_{AX}(\langle I_x^X \rangle - I_x^{\text{eq}})$$

$$- \sigma_{\text{CSA}(A),d}(2I_z^AX_z^X)$$

$$\frac{d}{dt}\langle I_x^X \rangle = -R_1^A(\langle I_x^X \rangle - I_x^{\text{eq}}) - \sigma_{AX}(\langle I_x^A \rangle - I_x^{\text{eq}})$$

$$- \sigma_{\text{CSA}(A),d}(2I_z^AX_z^X)$$

$$\frac{d}{dt}(2I_z^AX_z^X) = -R_1^AX_z^X(\langle I_x^X \rangle - I_x^{\text{eq}})$$

$$- \sigma_{\text{CSA}(A),d}(\langle I_x^A \rangle - I_x^{\text{eq}})$$

where $R_1^{AX}$ is the specific relaxation rate of longitudinal spin order and $\sigma_{\text{CSA}(A),d}$ is the interference term, expressed according to Equation (100):

$$\sigma_{\text{CSA}(A),d} = -\left(\frac{1}{5}\sqrt{\frac{7}{3}}(\gamma_A B_0)(\Delta \sigma_A) \frac{\mu_0}{4\pi}\right. \times \left.\frac{2\gamma_A \gamma_X h}{\mu_0^2 \mu^2} J(w)\right)$$

It enhances the CSA ($\Delta \sigma_A$ stands here for the shielding anisotropy of nucleus $A$; see section 3.3) mechanism and has been detected in numerous instances at high field. For instance, in proteins, it leads to the determination of carbon-13, nitrogen-15 and even proton chemical shift anisotropies. Analogous equations exist for transverse relaxation; they involve an interference term which, in the extreme narrowing, is equal to $7/6 \sigma_{\text{CSA}(A),d}$.

### 3.10 Quadrupolar Relaxation

Because the spin system (i.e. the quadrupolar nucleus) possesses more than two energy levels, a quantum mechanical treatment is required and, in general, the evolution of longitudinal and transverse magnetizations is not exponential. Additional quantities (in the same way as the longitudinal spin order for dipolar relaxation) may be necessary so as to describe completely the evolution provided that the NMR spectrum involves quadrupolar splittings (anisotropic medium).

If the environment of the considered nucleus is not of spherical symmetry, the quadrupolar mechanism is overwhelming. Some useful equations are given below.
1. In extreme narrowing conditions, $\tau_{1e}^{\text{eff}}$ describing the reorientation of the EFG tensor $z$-axis, longitudinal and transverse relaxations are purely exponential with (Equation 101):

$$
(R_1)_q = (R_2)_q = \left(\frac{3\pi^2}{10}\right) \left\{ \frac{2I + 3}{I^2(I-1)} \right\} \chi^2(1 + \eta^2)\tau_{1e}^{\text{eff}}
$$

where $I$ = spin number, $\chi = eQV_{zz}/h = \text{quadrupole coupling constant with } e = \text{electron charge, } Q = \text{quadrupolar moment, } V_{zz} = \text{either the largest element of the EFG tensor (which is supposed to be expressed in its PAS) or the element corresponding to the symmetry axis if the EFG tensor is axially symmetrical and } \eta_q = (V_{xx} - V_{yy})/V_{zz} = \text{symmetry parameter.}$

2. In the general case, the following approximations may be considered (Equations 102 and 103):

$$
(R_1)_q \approx \frac{2I + 3}{5} \left[ 8 q(2w_0) + 2 q(w_0) \right]
$$

$$
(R_2)_q \approx \frac{2I + 3}{5} \left[ 2 q(2w_0) + 5 q(w_0) + 3 q(0) \right]
$$

where the measurement frequency $\nu_0 = w_0/(2\pi)$, and Equation (104):

$$
q(w) = \left(\frac{3\pi^2}{40}\right) \left\{ \frac{1}{I^2(I-1)} \right\} \chi^2 \left(1 + \eta^2\right) \tilde{J}(w)
$$

These expressions are strictly valid for a spin-1 ($^3\text{H}, ^{14}\text{N}$).

3.11 Paramagnetic Relaxation

A spin-1/2 nucleus close to an unpaired electron is subjected to (i) the dipolar interaction (dipolar or pseudo-contact mechanism) or (ii) the hyperfine interaction (scalar relaxation of the second kind or contact mechanism). The fast relaxing nature of the electron spin must be taken into account in the effective correlation times (and also possible exchange phenomena) (Equations 105 and 106):

$$
\frac{1}{\tau_{ce}} = \frac{1}{T_{1e}} + \frac{1}{\tau_R} + \frac{1}{\tau_e} + \frac{1}{\tau_M}
$$

$$
\frac{1}{\tau_{ce}} = \frac{1}{T_{2e}} + \frac{1}{\tau_R} + \frac{1}{\tau_e} + \frac{1}{\tau_M}
$$

where $T_{1e}$ and $T_{2e}$ are electronic relaxation times, $\tau_R$ is the rotational correlation time (isotropic motion assumed) and $\tau_e$ and $\tau_M$ are electron and nucleus residence times in the case of exchange.

Denoting the electron resonance frequency by $w_e$ and realizing that $w_e \gg w_0$, one obtains Equations (107) and (108) for the dipolar contribution:

$$
(R_1)_d = K_d \left[ \frac{6\tau_{ce}}{1 + w_0^2\tau_{ce}} + \frac{14\tau_{ce}}{1 + w_e^2\tau_{ce}} \right]
$$

$$
(R_2)_d = K_d \left[ 4\tau_{ce} + \frac{3\tau_{ce}}{1 + w_0^2\tau_{ce}} + \frac{13\tau_{ce}}{1 + w_e^2\tau_{ce}} \right]
$$

For $K_d$, see $K_{AX}$ defined for the dipolar interaction, where $A$ here represents the nucleus and $X$ the electron.

For the scalar relaxation contribution of both kinds (first and second) with (Equations 109–111):

$$
\frac{1}{\tau_{ce}} = \frac{1}{\tau_{ce}} - \frac{1}{\tau_R}
$$

$$
\frac{1}{\tau_{ce}} = \frac{1}{\tau_{ce}} - \frac{1}{\tau_R}
$$

$$
K_{SC} = \frac{4\pi^2 A^2 S(S+1)}{3}
$$

where $A = \text{hyperfine coupling in hertz and } S = \text{spin number of the electronic system, one obtains Equations (112) and (113)}:

$$
(R_1)_{SC} = K_{SC} \left[ \frac{2\tau_{ce}}{1 + w_0^2\tau_{ce}} \right]
$$

$$
(R_2)_{SC} = K_{SC} \left( \tau_{ce} + \frac{\tau_{ce}}{1 + w_0^2\tau_{ce}} \right)
$$

4 INFLUENCE OF SPIN RELAXATION ON QUANTITATIVE MEASUREMENTS

It is clear from the above considerations that spin relaxation plays a central role in any NMR experiment. A few illustrative examples, dealing with quantitative measurements, are provided in this section. Many more examples can be found in two review articles.

4.1 Sensitivity Improvement and Repetition Rate

As already mentioned in the Introduction, NMR is very often impaired by poor sensitivity and this requires some remedy. In particular, it is well known that, after adding $n$ scans, the S/N improves by $\sqrt{n}$. The only issue concerns the time needed for performing $n$ scans. Roughly, a CW NMR spectrum is recorded in several minutes whereas an FID drops to an undetectable level in less than a few seconds (or milliseconds). This is why pulse NMR (or, in other words, FTNMR) has gained much popularity in the context of signal accumulation. The
shorter than 5

For any arbitrary

Of course, ideally one should measure $M_0 \sin \alpha$, which would require $T$ of the order of $5T_1$ so that $\exp(-T/T_1) = 0.01$. A compromise in terms of S/N is usually adopted through an optimum flip angle, $\alpha_{\text{opt}}$, also called the Ernst angle (Equation 115):

$$\cos \alpha_{\text{opt}} = \exp \left(-\frac{T}{T_1}\right)$$  \hspace{1cm} (115)

for any arbitrary $T$ value, but most of the time much shorter than $5T_1$. This entails again a bias as far as quantitative results are wanted (see Equation 114). Whenever $T_1$ is long, it must be reduced so that the condition $T \approx T_1$ can be fulfilled. Since paramagnetic relaxation (section 3.11) is very efficient, the usual trick consists in adding a very small amount of a paramagnetic substance, e.g. Cu(SO₄) or Cr(acac)₃ [tris(acetato)chromium] according to their ability to be dissolved in the solution under investigation. Sometimes, dissolved oxygen present in the solution may prove sufficient.

4.2 Polarization Transfer in Heteronuclear Systems

NMR spectroscopy of heteronuclei is generally performed under proton broad-band decoupling with the aim of simultaneously simplifying the spectrum and increasing the sensitivity since all lines within a multiplet (due to $J$ coupling with protons) coalesce into a single line. This is especially interesting for carbon-13 NMR at natural abundance level; in that case, the existence of two $^{13}$C isotopes within the same molecule can be disregarded and splittings due to the carbon–carbon coupling are not expected. Each carbon in the molecule thus appears as a single line, provided of course that no nuclear spins other than protons (e.g. $^{31}$P, $^{19}$F) are present. However, as already mentioned, broad-band decoupling implies the saturation of proton transitions (so as to mix proton spin states and thus suppress $J$ coupling effects), which leads to the NOE. As seen in section 3.8, the signal is enhanced by a factor equal to $1 + (\gamma_H/\gamma_C)(\sigma/R_C^T)$, where $\gamma_C$ and $\gamma_H$ are the carbon and proton gyromagnetic ratios, respectively, $R_C^T$ is the carbon longitudinal relaxation rate and $\sigma$ the cross-relaxation rate equal at most to $R_C^T/2$ (when extreme narrowing conditions prevail and when carbon relaxation is essentially of dipolar origin). Obviously, each carbon-13 in a given molecule has its own relaxation properties so that NOE enhancements are differentiated. For instance, a carbon bound to a proton is likely to benefit from a full NOE (in a small molecule) whereas the relaxation of a carbonyl is probably dominated by the CSA mechanism. Therefore, the carbonyl peak intensity is generally much less than that of an aliphatic carbon. Clearly, the quantitative aspect of carbon-13 spectroscopy is lost owing to the NOE. This undesirable feature combines with the loss of intensity arising from a repetition rate that is too high with respect to the longitudinal relaxation rate. Concerning NOE, the only remedy is to prevent its buildup by switching on the proton decoupler only during signal acquisition according to the scheme in Figure 31(a) and (b), where an example of a quantitative $^{13}$C spectrum is shown.

Furthermore, the repetition rate must be lengthened because switching the proton decoupler on and off entails a perturbation of the proton magnetization. As a consequence, complete return to thermal equilibrium depends not only on carbon relaxation but also on proton relaxation. Overall, it is recommended to settle the repetition rate at 10 times the carbon-13 $T_1$ (according to the Solomon equations) and not to five times (as would be the case according to the Bloch equations). Finally, it can be mentioned that the continuous application of proton decoupling can be devastating in the case of nitrogen-15 spectroscopy; because $^{15}$N and proton gyromagnetic ratios have opposite signs, this may lead to the disappearance of the $^{15}$N signal in unfavorable conditions of cross-relaxation rate vs specific relaxation rate.

4.3 Overlapping Patterns and Spectral Analysis

We shall be concerned here with signals which overlap in the frequency domain owing to their line width.
Figure 31 (a) A carbon-13 spectrum obtained under standard
conditions. Except the multiplet at 78 ppm (deuterated solvent),
each peak corresponds to one carbon in the same molecule.
Notice the differences in peak heights. (b) The same spectrum
obtained according to the sequence in the inset. All peak heights
are almost identical; the remaining small differences are due to
their line width (slight variations of the effective $T_2$) while peak
intensities are effectively identical.

If we disregard the line broadening by $B_0$ homogeneity,
this can occur because of large transverse relaxation
rates impairing the direct measurement of line intensities.
In that case a mathematical analysis must be

carried out so as to separate in one way or another
overlapping signals and thus pick up their individual
characteristics. For practical reasons and to avoid arti-
facts associated with Fourier transformation, this is
better performed in the time domain, that is, directly
on the FID. We shall not present the numerous sophis-
ticated methods, based on linear prediction or entropy
maximization,\(^48\) but rather rely on simple nonlinear least
squares,\(^49\) and consider the following target function

$$F = \sum_{j=1}^{N} \left( y_j - \sum_{k=1}^{K} A_k \exp[i(2\pi v_k t_j + \psi_k)] \exp(b_k t_j) \right)^2$$  \(116\)

where $y_j$ is the complex amplitude of the $j$th data point,
aquired at time $t_j$, and the subscript $k$ is associated with
one of the $K$ signals constituting the FID, assumed to
lead to a Lorentzian line after Fourier transformation.
$v_k$ is its frequency, $\psi_k$ a phase factor (depending on
instrumental conditions), $b_k = 1/T_{2k}$ the inverse of its
effective transverse relaxation time (including possibly $B_0$
inhomogeneity), and the quantity of interest, $A_k$, is the
signal amplitude in the time domain which corresponds to
the peak area in the frequency domain. These quantities
are obtained by an iterative calculation aiming at the
minimization of $F$ and using as initial parameters those
deduced from the Fourier transform of the FID. This
procedure is exemplified by spectra (corresponding to
the experimental and fitted FIDs) shown in Figure 32.

4.4 Partial Decoupling by Quadrupolar Nuclei

As reported in section 3.10, relaxation of nuclei of
spin $\geq 1/2$ is dominated by the so-called quadrupolar
mechanism, provided that the considered nucleus is not in a symmetrical surrounding. It can be recalled that this mechanism is generally highly efficient leading to remarkably short $T_1$ and $T_2$, and hence to broad lines. In this respect, relaxation produces fast switching between spin states and acts as a decoupler of the quadrupolar nuclei, with respect to the other nuclei (of spin-1/2). It is for this reason that one seldom observes $J$ splittings from nuclei such as $^{35}$Cl, $^{37}$Cl, $^{79}$Br, $^{81}$Br or $^{14}$N, and that the only effect of a nearby quadrupolar nucleus is the so-called "scalar relaxation of the second kind" (see section 3.4). Now, if the surrounding of the quadrupolar nucleus becomes more or less symmetrical, the quadrupolar mechanism is no longer overwhelming and becomes comparable to other contributions. In other words, $T_1$ and $T_2$ have much longer values. As a consequence, the decoupling effect tends to disappear and $J$ splittings due to the quadrupolar nucleus are retrieved. These features, which can make the determination of line intensities difficult, are illustrated in Figures 33 and 34.

**Figure 33** (a) The normal proton spectrum of formamide (with peaks broadened by $^{15}$N–$^1$H couplings). (b) The same spectrum obtained under $^{15}$N irradiation, which removes the effect of $^{15}$N–$^1$H couplings. Notice that splittings due to $^1$H–$^1$H couplings become visible. However, the remaining broadening is due to chemical exchange between the two amide protons resulting from the hindered rotation of the CN bond.

**Figure 34** A further example of visible $J$ couplings between $^1$H and $^{14}$N whenever the latter nucleus is in a quasi-symmetrical environment. Each line of the CH$_3$ triplet (the triplet is due to $^1$H–$^1$H $J$ coupling with the nearby CH$_2$) is further split into three lines of equal intensity due to the $J$ coupling with the $^{14}$N nucleus (which is a spin-1 nucleus, hence possessing three spin states, 1, 0 and −1).

1 INTRODUCTION

Direct magnetic dipole–dipole interaction between two magnetic nuclei can be shown to average out to zero in the isotropic fluid phase when the internuclear vector connecting these two nuclei randomly changes its spatial direction due to tumbling motions of the molecule on which they are embedded. Despite random molecular tumbling, however, it is usually found that the interaction between two magnetic nuclei is not always vanishing as manifested by the spectral splittings it causes. Hence this nonvanishing type of interaction can be thought to occur indirectly through mediation of electrons surrounding the two interacting nuclei, which we call nowadays indirect spin interaction (or coupling). This interaction was first observed by Proctor and Yu\(^{1}\) as magnetic-field-independent splitting due to the coupling between \(^{121}\)Sb and \(^{19}\)F of the SbF\(_6\)\(^-\) anion in an aqueous solution of NaSbF\(_6\). Shortly after this Gutowsky and McCall\(^{2}\) reported on the spin coupling between \(^{31}\)P and \(^{19}\)F in POCl\(_3\)F, POClF\(_2\), and CH\(_2\)OPF\(_2\) which was followed by Hahn and Maxwell\(^{3}\) with their report on H–H coupling in CHCl\(_2\)CHO. Based on their observations Gutowsky and McCall and Hahn and Maxwell independently proposed that the Hamiltonian \(H_{NN}\) describing this field-independent interaction in isotropic fluids should take the form of a scalar product as shown in Equation (1):

\[
h^{-1}H_{NN} = J_{NN} \mathbf{I}_N \cdot \mathbf{I}_{N'}
\]  

(1)

where \(\mathbf{I}_N\) and \(\mathbf{I}_{N'}\) are respectively, the spin angular momentum operators for the nuclear spins \(N\) and \(N'\) and \(J_{NN}\) is the isotropic spin–spin coupling constant for the given pair of spins. [When there are several coupling pairs of magnetic nuclei, it is understood that Equation (1) is pairwise added.]

However, as Ramsey\(^{4}\) pointed out, when the internuclear vector connecting the coupled nuclei is not randomly tumbling as it does in an isotropic fluid, the indirect spin interaction can depend on the spatial orientation of the internuclear vector with respect to the applied static magnetic field. The corresponding Hamiltonian expressed in the form of Equation (1) then should be modified to Equation (2):

\[
h^{-1}H_{NN} = \mathbf{J}_{NN} \cdot \mathbf{I}_N \cdot \mathbf{I}_{N'}
\]  

(2)

where \(\mathbf{J}_{NN}\) is a second-rank tensor called the indirect spin coupling tensor.

The indirect spin coupling tensor may be written like any other tensor of rank 2 as a sum of two parts, the symmetric and the antisymmetric part,\(^{5}\) as shown in Equation (3)

\[
\mathbf{J}_{NN} = \mathbf{J}_{NN}^{\text{sym}} + \mathbf{J}_{NN}^{\text{anti}}
\]  

(3)

where the symmetric part \(\mathbf{J}_{NN}^{\text{sym}}\) is defined by Equation (4):

\[
\mathbf{J}_{NN}^{\text{sym}} = \frac{1}{2}(\mathbf{J}_{NN} + \mathbf{J}_{NN}^T)
\]  

(4)
while the antisymmetric part $J_{NN}^{\text{anti}}$ may be expressed by Equation (5):

$$J_{NN}^{\text{anti}} = \frac{1}{2}(J_{NN} - J_{NN}^T)$$  (5)

with $J_{NN}^T$ denoting the transpose of $J_{NN}$. This tensor is antisymmetric with respect to exchange of row and column, whence its diagonal elements are all zero. For convenience the symmetric part $J_{NN}^{\text{sym}}$ is also divided into the isotropic part $J_{NN}^{\text{iso}}$ and the traceless part $J_{NN}^{\text{sym}(0)}$ which are defined, respectively, by Equations (6) and (7):

$$J_{NN}^{\text{iso}} = \left(\frac{1}{3}\text{Tr}(J_{NN})\right)1$$  (6)

$$J_{NN}^{\text{sym}(0)} = \frac{1}{2}\left(J_{NN} + J_{NN}^T\right) - J_{NN}^{\text{iso}}$$  (7)

where $\text{Tr}J_{NN}$ is the sum of three diagonal elements of the tensor $J_{NN}$ while $I$ denotes the unit tensor. To the first-order approximation we may concern ourselves only with the symmetric part of $J_{NN}$ tensor because the contribution from the antisymmetric part becomes appreciable only in second- or higher-order calculation. Thus one may replace the full tensor $J_{NN}$ by its truncated form $J_{NN}^{\text{iso}} + J_{NN}^{\text{sym}(0)}$, which is symmetric and can be diagonalized, in our ensuing discussion.

Let us denote the three principal components of $J_{NN}$ by $J_{xx}$, $J_{yy}$, and $J_{zz}$ (dropping the subscript $NN$ for brevity), with the convention shown in Equation (8):

$$|J_{zz}| \geq |J_{xx}| \geq |J_{yy}|$$  (8)

In order to describe the orientation dependence of NMR parameters it is convenient to define the anisotropy of that particular parameter. In the case of the indirect spin–spin coupling tensor we usually define its anisotropy by Equation (9):

$$\Delta J \equiv J_{zz} - \frac{1}{2}(J_{xx} + J_{yy})$$  (9)

One of the easily tractable cases is when the two coupling nuclei are located on an axis of cylindrical symmetry, for which one may write Equation (10):

$$J_{zz} = J_\parallel \text{ and } J_{xx} = J_{yy} = J_\perp$$  (10)

Therefore, in the presence of axial symmetry Equation (9) takes the form shown in Equation (11):

$$\Delta J = J_\parallel - J_\perp$$  (11)

In this case the Hamiltonian (Equation 2) may be expressed by Equation (12):

$$\hbar^{-1}H_{NN} = I_N \cdot I_N + I_\perp \cdot J' \cdot I_N$$  (12)

where the scalar spin coupling constant $J$ means $\frac{1}{2}\text{Tr}(J_{NN})$ and the traceless tensor $J'$ is given by Equation (13):

$$J' = -\frac{1}{3}J \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}$$  (13)

In fluid phases the anisotropic part in the Hamiltonian (Equation 12) involving the tensor $J'$ averages out to zero due to random tumbling of the principal-axes frame of this tensor, and only the isotropic part of $J$ survives and affects the appearance of NMR spectra for the given spin system. The term ‘‘scalar coupling’’ invariably refers to the isotropic part of indirect spin coupling because it can be expressed in the form of a scalar product of spin angular momentum vectors of the two coupling nuclei. Based on the Hamiltonian (Equation 12) one may derive an expression explaining the spectral splitting caused by the indirect spin coupling which depends on the angle between the applied static field and internuclear axis. Thus, in principle one can obtain information on $J$ and $\Delta J$ by observing the spectral splittings due to indirect spin coupling in single crystals or powder samples as a function of this angle and in this way these parameters have been measured and reported for some molecules. However, the anisotropic part of $J$ transforms exactly like direct magnetic dipole–dipole interaction and, therefore, it will be difficult to disentangle the effect of the former from that of the latter and due to this accurate data on $\Delta J$ are rare. Over the last 45 years most information on indirect spin coupling has been obtained mainly from the isotropic part and correlated with molecular structure in the liquid state. Therefore, in this article attention will be paid only to the isotropic part of $J$.

2 THEORY OF SCALAR SPIN COUPLINGS

Shortly after the discovery of indirect nuclear spin–spin coupling, a suitable quantum mechanical interpretation for the mechanism of this interaction was provided for the first time by Ramsey and Purcell, and later by Ramsey in greater detail. For heavier nuclei the relativistic effect will undoubtedly be important, but we restrict ourselves here to Ramsey’s nonrelativistic description of indirect spin couplings. Although formal mathematical expressions for scalar spin coupling constants may be derived on the basis of perturbation theory, actual evaluation of these parameters from the derived expressions is a formidable task because we have little knowledge of the exact wavefunctions of the electronically excited states. Nevertheless, we can draw some qualitatively correct conclusions without performing complicated quantum mechanical calculations with the help
SCALAR COUPLINGS IN NUCLEAR MAGNETIC RESONANCE, GENERAL

Figure 1 Dirac vector model for (a) directly bonded coupling and (b) geminal coupling between H and D in (a) HD and (b) HDO.

of a few assumptions and semiempirical results, which we will describe in the ensuing discussion.

Ramsey has proposed that Fermi contact interactions between the nuclei and electrons provide the major source of contribution to indirect spin coupling. When an electron occupies an s-orbital, it has nonvanishing density at the nuclear site. This causes the so-called contact interaction which was first studied by Fermi. How the indirect spin coupling is brought forth by the contact interaction may be understood in the following manner. The contact interaction favors the antiparallel orientation of an electron spin at a nuclear spin if the magnetogyric ratio of the nucleus is positive; in other words, the electron and nuclear magnetic moments are stable when parallel. Also, we note that electrons occupying the same orbital tend to have their spins aligned antiparallel (Pauli interaction) while those in the different orbitals favor the parallel spins (Hund-type interaction).

Based on this simple model we are able to provide some physical pictures of scalar coupling transmitted through chemical bonds. First, consider a diatomic molecule, say, HD. This system of two directly bonded nuclei shown in Figure 1(a) becomes stabilized by having two nuclear spins antiparallel. In this case we say J is positive. (In general, J is not always positive for a pair of coupled nuclei.) The same logic may be applied to the case where there is an intervening atom between the two coupled nuclei to predict that J will be negative (Figure 1b) and smaller in magnitude compared with the case of directly bonded nuclei because correlations between electrons occupying different orbitals are expected to be less than those between electrons occupying the same orbital. This contact mechanism is important for (H, H) coupling because the electron densities about electrons are well represented by 1s atomic orbitals and may be extended further to the case of a larger number of bonds and we may anticipate that the sign of J alternates while its magnitude decreases rapidly as the number of intervening bonds increases. This simple model is based on the assumption that J coupling is transmitted through bonding σ electrons and the nucleus–electron interaction is dominated by the contact interaction. Although this model, frequently referred to as the Dirac vector model, is an oversimplification of the actual situation and there are invariably contradicting exceptions, it provides some qualitative explanation of general trends in variation of sign and magnitude of J. For example, for saturated hydrocarbons, (H, H) coupling is rarely observed when two protons are separated from each other by more than four or five bonds, but the attenuation of the magnitude of J is known to be less steep than the Dirac model would suggest.

To distinguish between number of intervening bonds we adopt the convention that we add a superscript prefix to the symbol J. Thus coupling between directly bonded nuclei is denoted by \( J^1 \) and coupling through two and three bonds, often known as geminal and vicinal coupling, is indicated by \( J^2 \) and \( J^3 \), respectively. The interproton coupling constant for the H₂ molecule is known to be \( J^1_{HH} = 284 \text{ Hz} \) while the geminal (H, H) coupling constant for the CH₂ group in saturated hydrocarbons ranges from \(-9\) to \(-21\) Hz, which is over an order of magnitude smaller than \( J^1_{HH} \). Clearly, the Dirac model fits well in this case. However, when the intervening carbon atom is sp² hybridized, it is known that \( J^2_{HH} \) is normally positive. This indicates that coupling through more than one bond may involve delocalization of electrons in contradiction to the Dirac vector model. Vicinal (H, H) coupling constants are of the same order of magnitude as geminal coupling constants but their signs are always positive. Frequently, we encounter the situation \( |J^2_{HH}| < |J^1_{HH}| \), which means the rationale behind indirect spin coupling is not as simple as the Dirac model may suggest.

The quantum mechanical perturbation treatment leads to Equation (14) for the contribution to J from the contact mechanism:

\[
J^c_{NN} = \frac{8\mu_\alpha^2\mu^2_B}{9\pi} \gamma_N \gamma_N \sum_{n(\neq 0)} \sum_k \sum_j \frac{1}{E_n - E_0} \times \langle 0|\delta(r_N)\hat{S}_k|n\rangle \cdot \langle n|\delta(r_N)\hat{S}_j|0\rangle \tag{14}
\]

where \( |0\rangle \) and \( |n\rangle \) are respectively, the ground spin singlet state and the excited spin triplet state with \( E_0 \) and \( E_n \) denoting the corresponding energy eigenvalues. Other notations appearing in Equation (14) have the following meanings: \( \mu_\alpha \) is the magnetic permeability of a vacuum, \( \mu_B \) is the Bohr magneton, \( \gamma_N \) is the magnetogyric ratio of nucleus N, \( \hat{S}_j \) is the spin angular momentum operator for
electron $j$, $r_{jN}$ is the position vector of electron $j$ relative to nucleus $N$, and $\delta(r_{jN})$ is the Dirac delta function of $r_{jN}$.

Although less dominant than the contact mechanism, the direct magnetic dipolar interaction of the nucleus with surrounding electrons can also be shown to make a contribution to $J$. That is, the magnetic moment of one of the coupled nuclei directly interacts with that of an electron spatially close to (but not in contact with) it which then correlates with another electron whose magnetic moment directly interacts with that of the other nucleus. This type of contribution can be shown to have the form shown in Equation (15):

$$J_{NN}^d = -\frac{\mu_0^2 \mu_r^2 \hbar}{24\pi^3} \gamma_N \gamma_N' \sum_{n\neq n'} \sum_k \sum_j \frac{1}{E_n - E_0} \times \langle 0|3(S_k \cdot r_{kN})r_{kN}^r_{jN}^r - S_j^r \delta(r_{kN})|n\rangle \times \langle n|3(S_j \cdot r_{jN})r_{jN}^r_{kN}^r - S_k^r \delta(r_{jN})|0\rangle$$

Besides the contributions via interaction between nuclear spin and electron spin there can be another type of contribution to $J$ as Gutowski et al. have shown. That is, the electronic orbital motions induced by the magnetic moment of one nucleus may interact with the magnetic moment of the other nucleus in such a way that interaction between these two nuclei might not be averaged to zero by random molecular motions. The formal expression for this type of contribution obtained by the perturbation treatment is given by Equations (16) and (17):

$$J_{NN}^p = \frac{\mu_0^2 \mu_r^2 \hbar}{48\pi^3 m} \gamma_N \gamma_N' \sum_k \sum_j \frac{1}{E_n - E_0} \times \langle 0|m_kN \cdot r_{kN}^r_{jN}^r - r_{kN}^r_{jN}^r m_jN|n\rangle \times \langle n|m_jN \cdot r_{jN}^r_{kN}^r - r_{jN}^r_{kN}^r m_kN|0\rangle$$

$$m_kN = -\frac{e}{2m} \mathbf{r}_{kN} \times \left(\frac{\hbar}{\ell}\right) \nabla_k$$

and $m$, $e$, and $\nabla_k$, respectively, stand for mass and charge of an electron and the gradient operator acting on the coordinates of electron $k$. Note that $J_{NN}^p$ in Equation (16) consists of two parts: one-electron and two-electron contributions. Physically, the one-electron parts arise because nuclear $N$ induces a local electron perturbation, producing a magnetic field which then acts across space on the second nucleus. The two-electron parts, on the other hand, arise because one nucleus induces a perturbation on its own atom, which in turn affects the distribution of a second electron on the other atom, and so on the second nucleus.

As mentioned earlier, exact calculation of the contributions to the scalar coupling constant from various sources on the basis of Equations (14), (15) and (16) is difficult unless the exact wavefunctions for the excited states are known. Thus, in earlier studies the so-called AEE (average excitation energy) approximation was adopted to alleviate this difficulty, in which the energy difference $E_n - E_0$ appearing in the above expressions for contributions to $J$ is replaced by an AEE $\Delta E$ regardless of $n$.

Ramsey has considered only the contact term to derive Equation (18) giving $J_{HD}$ for a HD molecule on the basis of the AEE and electronic ground state function reported by James and Coolidge:

$$J_{HD} = \frac{2\mu_0^2 \mu_r^2 \hbar}{3\pi} \gamma_N \gamma_D \Delta E \frac{1}{S_H(0)^2 S_D(0)^2} = 758.9 \Delta E \text{ (Hz)}$$

where $S_H(0)^2 S_D(0)^2$ is the electron density on the coupled proton and deuteron and $\Delta E$ the singlet–triplet excitation energy expressed in electron-volt units. A reasonable value of $\Delta E \approx 19.0$ eV gives a coupling constant of 40 Hz, which is close to the experimental value of 42.94 Hz. This indicates that the contribution from the contact term dominates those from other terms in the case of $J_{HD}$. A few years later, McConnell and others proposed another scheme based on the valence bond (VB) method. In both approaches the AEE approximation was adopted. Within the frame of AEE approximation both the MO method and the VB method predict that the contribution from the contact mechanism is proportional to $\gamma_N \gamma_N' S_N(0)^2 S_N(0)^2$ where $S_N(0)^2$ denotes the density at the nucleus $N$ of the valence s-electrons.

Coupling constants involving heavier nuclei are usually much larger than $J_{HH}$. For example, it was reported that $J(\text{199Hg}, \text{31P}) = 9.66$ kHz and $J(\text{205Tl}, \text{11C}) \approx 1$ kHz. This is mainly due to the fact that for heavier nuclei the valence s-electron density is much higher than for protons. But other mechanisms are also known to make substantial contributions in the case of heavier nuclei. To date, however, most extensively investigated and best understood from a theoretical point of view are the couplings between nuclei comprising organic molecules, and we will concern ourselves mainly with these nuclei.

The AEE approximation greatly simplifies the calculational procedure but is not always justified. Later, the calculations were carried out without invoking this approximation by Pople and others, primarily using the MO expressions arising from Rayleigh–Schrödinger’s “sum over states” method, finite perturbation theory, and self-consistent perturbation theory. A general VB approach developed by Karplus et al. was also successfully applied to the interpretation of the dependence of (H, H) vicinal couplings on the dihedral angle and of geminal coupling on the bond angle between the coupled
protons. However, mathematical difficulties associated with the VB method have made it less readily applicable than the MO approaches for calculation of spin–spin coupling constants. Until Barfield\(^{(15)}\) proposed a new method based on the transition spin-density formulation, all the VB approaches had resorted to the AEE approximation. Theoretical calculations of coupling constants based on the various methods published thus far have all yielded results that agree qualitatively with experimental values both in sign and magnitude and can be helpful for understanding the nature of bonding and stereochemistry in relevant molecules. According to these calculations the contact term generally seems to be dominant for \(^1J(C, H)\) and \(^1J(C, C)\) coupling. However, orbital and dipolar contributions become significant for \(^1J\) coupling involving multiple-bonded carbon atoms, fluorine, and other heavier atoms. We will not duplicate these data here and interested readers are referred to other NMR literature.\(^{(16–20)}\)

In view of expressions for \(J\) derived thus far (see Equations 14, 15, and 16) it is obvious that \(J\) is proportional to the product of magnetogyric ratios of a coupled pair of nuclei. This is because all the interactions contributing to the indirect spin coupling are of magnetic origin and involve products of nuclear magnetic moments. This enables us to evaluate the coupling constants between magnetically equivalent nuclei. (See section 4 for the meaning of magnetic equivalence.) The couplings between magnetically equivalent nuclei cannot be directly observed because they cannot affect the NMR spectra. For example, for the \(H_2\) molecule we cannot observe splitting of the proton absorption due to scalar spin coupling between two protons because they are magnetically equivalent. However, substitution of one of the two protons by a deuteron will result in splitting of the proton absorption line, from which we can measure \(|J_{HD}|\). The observed value of \(|J_{HD}|\) is known to be 42.94 Hz. Then, by making use of Equation (19):

\[
\frac{J_{HH}}{J_{HD}} = \frac{\gamma_H}{\gamma_D} = 6.514
\]

we have \(|J_{HH}| = 279.7\) Hz.

Adapted from Table 8–13 in Harris.\(^{(16)}\)

Because of the fact that \(J\) is proportional to the product of magnetogyric ratios of the coupled pair of nuclei comparison between coupling constants of different elements will be meaningful only when the effect of magnetogyric ratios is eliminated. For this purpose one may define reduced coupling constants, usually denoted by \(K\), using Equation (20):

\[
K_{NN} = \frac{4\pi^2 J_{NN}}{h\gamma_N \gamma_N'}
\]

Since the dependence on magnetogyric ratios has been eliminated, \(K\) shows better correlation with the variation of atomic number in a group.\(^{(16)}\) For example, as shown in Table 1, the data for \(^1J_{XI}\) in group IV elements (C, Si, Ge, Sn) show no trend in variation, even changing irregularly in sign. However, those for \(^1K_{XI}\) for the same elements show a smooth trend, increasing with the atomic number \((Z_X)\) of X. In fact, there has been an attempt to establish a universal relationship between \(^1K_{XY}\) in isostructural molecules containing isoelectronic valence shells for the relevant atoms. Considering that the contact term is dominating and the relative coupling constants depend on the square of atomic s-electron charge densities at each nucleus, Reeves et al.\(^{(21–23)}\) have proposed the relationship shown in Equation (21) for a given nucleus Y:

\[
\sqrt{K_{XY}} = aZ_X + b
\]

Equation (21) is known to be obeyed poorly if one of the coupling nuclei is fluorine or a heavy metal.

### 3 CORRELATION WITH MOLECULAR PROPERTIES

It is known that there are several factors influencing the sign and magnitude of the coupling constant and in this section we will discuss them in conjunction with molecular structure.

#### 3.1 Coupling between Directly Bonded Nuclei

Ramsey’s result (Equation 18) suggests that the nature of bonding can be understood by means of spin–spin coupling when the contact term is of greatest importance. Thus, it is not surprising that the relation shown in Equation (22) was proposed for \(^1J(\text{^{15}N} – \text{^{13}C})\):\(^{(24)}\)

\[
|\text{^1}J(\text{^{15}N} – \text{^{13}C})| \propto \%S_C \%S_N
\]

where \(\%S_C\) and \(\%S_N\) are the percent s-character of the atomic orbitals forming the \(\sigma\) bond between the \(^{15}\)N and \(^{13}\)C nuclei. Finite perturbation theory/intermediate...
neglect of differential overlap calculations developed by Pople et al.\textsuperscript{143} show that the proportionality constant in Equation (22) should be 0.0106 and the sign of the coupling constant should be negative. (However, the same calculation shows that the contact term is not as dominant as in the case of $J_{HH}$.) Similar relations were also proposed. For example, for $^{13}$C–H and $^{13}$C–$^{13}$C coupling Equations (23)\textsuperscript{(25)} and (24)\textsuperscript{(26,27)} were proposed, respectively:

1

1

For a highly strained ring system Newton et al.\textsuperscript{(28–30)} proposed, instead of Equation (23), Equation (25):

$J(13C_1-13C_2) = 0.0621 \%S_{C_1} \%S_{C_2} - 10.2$ \hfill (25)

Equation (23) indicates that hybridization of the carbon atom is important and is helpful for estimating the s-character of the C–H bond. For example, for the sp$^3$ bond as in methane and ethane \%S is $\frac{1}{4}$, i.e. 25\%, whence $J_{CH} = 125$ Hz, and for sp$^2$ and sp, as in ethylene and acetylene, \%S are $\frac{1}{2}$ and 1, respectively, with the corresponding one-bond coupling constant being 167 and 250 Hz. Measured coupling constants for ethane, ethylene, and acetylene are known to be 124.9, 156.4, and 248.7 Hz, respectively. Although the relation does not yield quantitatively satisfactory results, its use for qualitative estimation is thus justified. Introduction of an electronegative substituent usually increases $J_{CH}$ by increasing the s-character of the C–H bond and this effect is usually additive, but multiple substitution by highly electronegative groups induces some deviation from the trend of additivity, for which we need the introduction of some extra terms to account for pairwise interactions between substituents.

3.2 Geminal and Vicinal Coupling

Of particular interest are $J_{HH}$ and $J_{HH}$ because of their dependence on bond angles. Experiments show that in hydrocarbons geminal $J_{HH}$ increases algebraically with increasing H–C–H bond angle, which was also confirmed by theoretical calculations. In sp$^3$ carbon, as in methane derivatives, $J_{HH}$ is negative while it takes a positive value for sp$^2$ carbon (−12.4 Hz for CH$_4$ and +2.5 Hz for CH$_2$=CH$_2$). The $J_{HH}$ values are known to be influenced by both \( \alpha \) and \( \beta \) substituents.

Substitution of an electronegative group into the methylene group in question (\( \alpha \) substitution) induces a positive change in the coupling constant. For example $J_{HH}$ is −10.8 Hz for CH$_2$Cl and −7.5 Hz for CH$_2$Cl while it is −12.4 Hz in CH$_4$. In polysubstituted methanes the effect of substituents is, to a first approximation, additive as in the case of $J_{CH}$ for the same molecule. Nonbonding electron pairs that can be seen in the substituents containing nitrogen and oxygen atoms usually induce a positive change in $J_{HH}$, which is illustrated by a large positive geminal (H, H) coupling constant in formaldehyde (+41 Hz). Steric orientation of these nonbonding electron pairs relative to the orientation of C–H bonds is also known to influence the coupling constant in the case of sp$^3$ hybridized methylene groups. In contrast to the case of \( \sigma \) substitution, an electronegative \( \beta \) substituent is known to result in a negative change in the coupling constant, while an electropositive \( \beta \) substituent produces opposite results. For instance, the $J_{HH}$ in CHF=CH$_2$ and LiCH=CH$_2$ are respectively, found to be −3.2 and +7.1 whereas that for CH$_2$=CH$_2$ is +2.5 Hz.

Thus far, we have been concerned mainly with transmission of $J$ coupling through \( \sigma \) electrons; however, neighboring \( \pi \) electrons are also known to have a considerable influence on the magnitude of the geminal coupling constant. They are known to induce a negative change. [Note that methane has $J = -12.4$ Hz while N≡C–CH$_2$–C≡N (malononitrile) has $J = -20.4$ Hz.] As in the case of nonbonding electron pairs, the \( \pi \) bond effect is known to be a function of the angle \( \varphi \) between the \( \pi \) orbital and the C–H bond. The largest effect is observed when the neighboring \( \pi \) orbital and the plane of the methylene group are parallel.

The (H, H) vicinal couplings in ethane and ethylene derivatives have attracted much attention from chemists because of their importance in studying the molecular structure of these and related compounds and extensive data for these coupling constants are now accumulated and available. Both theoretical and experimental results show that the vicinal (H, H) coupling constants in H–C–C–H molecular fragments are invariably positive, in agreement with the simple Dirac vector model. In fact, the signs of other coupling constants are often determined relative to that of $J_{HH}$ which is always assumed to be positive. The vicinal coupling constants between H and other nuclei are also normally positive although $J_{FF}$ values are known to be negative.

One of the most conspicuous features in the context of $J_{HH}$ is its dependence on the H–C–C–H dihedral angle \( \varphi \). This dependence, first theoretically predicted by Karplus\textsuperscript{31} on the basis of VB theory and now called the Karplus equation, is usually expressed as in Equation (26):

$J_{HH} = A + B \cos \varphi + C \cos 2\varphi$ \hfill (26)

where \( \varphi \) is the dihedral angle for this system (Figure 2). A typical set of values for the parameters $A$, $B$, and $C$ for hydrocarbons are 7, −1, and 5 Hz, respectively, but FTP-INDO calculations give a somewhat different
set of values for ethane ($A = 8.436$, $B = -2.835$, and $C = 7.523$ Hz respectively). The validity of the Karplus equation shown in Equation (26) is justified by many experimental examples. For instance, in ethylene $J_{\text{trans}}^{\text{HH}}$ $(=19.1$ Hz, $\varphi = \pi)$ is greater than $J_{\text{cis}}^{\text{HH}}$ $(=11.6$ Hz, $\varphi = 0)$ and $J_{\text{axial-axial}}^{\text{HH}}$ $(\varphi \approx \pi)$ is greater than $J_{\text{axial-equatorial}}^{\text{HH}}$ $(\varphi \approx \pi/3)$ in cyclohexane derivatives. Theory has shown that this dihedral angle dependence comes from electron spin correlation between electrons in different bonds and the most important exchange integral deciding this correlation is that between vicinal orbitals. This causes the electrons to be stable when their spins are antiparallel, thus leading to a positive vicinal coupling constant. The Karplus equation means that overlap of two vicinal orbitals is optimal when the C–H bonds are mutually cis and trans and this overlap is slightly greater for trans bonds than for cis bonds. If the molecule of interest has rapidly changing fluxional structure, only values averaged over various possible conformation are observed. As an example, we may consider a molecule of the type CH$_2$CHXY for which the observed $J_{\text{HH}}$ is $\frac{1}{2}J_x + \frac{1}{2}J_t$, where $J_x$ and $J_t$ are the gauche and trans coupling constants, respectively (Figure 3).

The $J_{\text{HH}}$ values in both the saturated and unsaturated H–C–C–H fragment are also affected by the presence of substituents. One tendency is that the substitution of an electronegative atom causes a decrease in the average coupling. For quantitative purposes it is usually attempted to correlate $J_{\text{HH}}$ with the electronegativity change $\Delta E = E(X) - E(H)$ caused by the replacement of a hydrogen atom by a group X. Thus, for saturated and unsaturated H–C–C–H fragments the following empirical relations shown in Equations (27) and (28) have been found to be valid:\(^{(18)}\)

$$J_{\text{HH}} = 9.41 - 0.80\Delta E \quad (\text{for H}_2\text{C–CH}_2\text{X}) \quad (27)$$

and

$$J_{\text{HH}}^{\text{trans}} = 19.0 - 3.3\Delta E \quad (\text{for H}_2\text{C–CHX}) \quad (28a)$$

$$J_{\text{HH}}^{\text{cis}} = 11.7 - 4.7\Delta E \quad (\text{for H}_2\text{C–CHX}) \quad (28b)$$

The substituent effect is also known to depend on dihedral angle $\varphi$ and the effect is greatest (that is, $3J$ has the smallest value) when the substituent X is trans to one of the coupled protons.

The Karplus-type equations have also been proposed for a pair of nuclei other than the (H, H) pair such as ($^{13}$C, $^1$H), ($^{13}$C, $^{13}$C), and ($^{31}$P, $^{13}$C), which have reasonable validity provided that closely similar compounds are treated, multiple-bonded atoms are excluded and the coupled nuclei do not possess lone pairs. For example, for hydrocarbons Equation (29) has been proposed:\(^{(32)}\)

$$3J^{(13}\text{C}, \text{H}) = 3.81 - 0.90\cos\varphi + 3.83\cos2\varphi \quad (29)$$

Other factors influencing $3J$ are H–C–C valence angles and C–C bond length. Increase of either of the two factors or both of them is known to decrease $3J$. Although the Karplus equation is very useful for estimating dihedral angles in compounds of unknown conformation, this relation should not be indiscreetly relied on because it is only valid in the absence of electronegative substituents and of distortion of tetrahedral angles at carbon. Only when values of $A$, $B$, and $C$ are determined from model compounds closely related to the unknown can the Karplus relation be useful in a qualitative sense. Even so, it is not usually recommended to use this relation for quantitative prediction of dihedral angles.

### 3.3 Long-range Coupling

Couplings between two spins which are four or more bonds away from each other are usually classified as long-range couplings. The magnitude of (H, H) coupling constants in this class ranges from 0.1 to 3.0 Hz, much smaller than geminal and vicinal coupling constants which usually have values of 5–20 Hz. Nowadays, it is not difficult to measure 0.2 or smaller splittings.

---

**Figure 2** Dihedral angle in hydrocarbon chain and angular dependence of Karplus relation (calculated setting $A$, $B$, and $C$ equal to 7, −1, and 5 Hz, respectively).

**Figure 3** Gauche and trans coupling in the CH$_2$CHXY molecule.
due to long-range couplings which are important for obtaining a wealth of information regarding structure and/or conformation of molecules.

In acyclic hydrocarbons $3J_{HH}$ or higher coupling constants are normally too small to be measurable, but in saturated cyclic hydrocarbons these coupling constants are often found to be of considerable magnitude when two CH bonds involving coupling protons lie on a plane of zigzag carbon chain as shown in (1) and (2). One such example can be seen in coupling over four bonds between two equatorial protons in six-membered saturated rings. In other words, long-range couplings (mediated by $\sigma$ electrons) between two protons are often highly stereospecific.

$$\text{H}_2\text{C} \cdot \text{C} \cdot \text{C} \cdot \text{H} \quad \text{(1)}$$

$$\text{H}_2\text{C} \cdot \text{C} \cdot \text{C} \cdot \text{H} \quad \text{(2)}$$

In order to understand how such a stereospecific long-range coupling arises let us consider the arrangement shown in (1) which is often called the “W” or “M” arrangement. Stereospecificity of long-range couplings indicates that direct spin correlation between electrons in vicinal orbitals, which we will henceforth refer to as vicinal orbital interaction, plays an important role. There may be several coupling pathways for the W arrangement. First, the C–H bonding $\sigma$ orbital interacts with the neighboring geminal C–C bond orbital which then undergoes vicinal interaction with the C–H orbital at the other end, which makes a positive contribution to $4J_{HH}$. Another coupling pathway consisting of two consecutive vicinal coupleings between three C–H orbitals may also be possible, which gives a negative contribution to $4J_{HH}$. The total coupling constant may therefore be positive or negative depending on which pathway dominates. However, considering that vicinal orbital interaction is maximum when the interacting orbitals are mutually trans, the first coupling pathway will probably weigh more in the W arrangement than the second, giving a positive sign of $4J_{HH}$. When there are several zigzag pathways like the W arrangement discussed above, the magnitude of $4J_{HH}$ rapidly increases as the number of pathways increases. Several such examples are shown in (3–8).

3.4 Coupling through $\pi$ Electrons

In unsaturated compounds not only $\sigma$ electrons but $\pi$ electrons as well seem to be involved in the $J$ coupling mechanism. For these compounds the observed coupling constants may be considered as the sum of the contributions from the $\sigma$ and $\pi$ mechanism, that is, $J^\sigma + J^\pi$. At first, this may seem puzzling because the $\pi$-electron distributions have nodes at the nuclei and, therefore, cannot contribute to $J$ directly through contact terms. McConnell has pointed out that $\pi$ electrons can contribute to $J$ through the $\sigma$–$\pi$ exchange mechanism as in the case of hyperfine coupling between unpaired $\pi$ electrons and nuclei in the electron spin resonance (ESR) of free radicals. Hence, the contribution to $J$ from $\pi$ electrons may be expressed in terms of the hyperfine coupling constant $a$ as shown in Equations (30–32):

$$\text{HC} = \text{CH} \text{ (ethylenic)} : 3J^\pi \propto a(=\text{CH}) a(=\text{CH}) \quad (30)$$

$$\text{HC} = \text{C} = \text{CH} \text{ (allylic)} : 4J^\pi \propto a(=\text{CH}) a(=\text{C} = \text{CH}) \quad (31)$$

$$\text{HC} = \text{C} = \text{C} \text{ (homoallylic)} : 5J^\pi \propto a(=\text{C} = \text{CH}) a(=\text{C} = \text{CH}) \quad (32)$$

The $\pi$ electron on ethylenic carbon induces negative electron spin density on the proton whereas $a(=\text{CH})$ is negative. This enables us to predict from Equation (30) that $3J^\pi$ will be positive. On the other hand, the $\pi$ electron on the allylic carbon favors parallel alignment of the s-orbital electron in the H atom, making $a(=\text{C} = \text{CH})$ positive. It is known from ESR measurement that $a(=\text{C} = \text{H}) \approx -6.5 \times 10^5$ Hz and that $a(=\text{C} = \text{C} = \text{H}) \approx 15 \cos^2 \varphi \times 10^3$ Hz, where $\varphi$ is the angle by which the C–H bond is tilted away from the axis of the p-orbital on allylic carbon. Thus, one may expect that $3J^\pi$ and $4J^\pi$ would be positive while $4J^\pi$ should be negative. Furthermore, we see that $J$ is not affected by orientation about a double bond. Thus, cisoid allylic $4J^\pi$ should equal transoid allylic $4J^\pi$. Acetylenic carbon $\pi$ electron also favors antiparallel alignment of the s-electron in the H atom as in the case of ethylenic coupling.
Since \( \pi \)-electron systems are often delocalized, spin correlation may occur for electrons at atoms separated by many chemical bonds. In other words \( \pi \) electrons provide a mechanism for long-range couplings. For example, \( \text{\(^3J_{Fy}\)} \) in butatriene is known to be as large as \( \pm 8.95 \text{ Hz} \) for both cis and trans forms. In 1,3-butadiene \( \text{\(^4J_{HH}\)} (\approx -0.83 \text{ Hz}) \) is nearly equal to \( \text{\(^4J_{trans}\)} (\approx -0.86 \text{ Hz}) \) and \( \text{\(^5J_{HH}\)} (\approx +0.69 \text{ Hz}) \) is very close to \( \text{\(^5J_{trans}\)} (\approx +0.60 \text{ Hz}) \) which, together with the signs of these coupling constants, indicates that the \( \pi \) contribution is dominant. However, \( \text{\(^5J_{trans}\)} (\approx +1.30 \text{ Hz}) \) has an appreciable contribution (almost 50\%) from the \( \sigma \) mechanism due to the zigzag conformation. This should be compared with ethylenic vicinal coupling for which \( J \) is known to constitute approximately only 10\% of the total coupling constant. One dramatic example that demonstrates the long-range nature of \( \pi \)-electron coupling is \( \text{CH}_2\text{C}==\text{C}==\text{C}==\text{C}==\text{CH}_2\text{OH} \), where the coupling constant between the methyl proton at one end of the molecule and the hydroxyl proton at the other end is known to be \( +0.4 \text{ Hz} \) which comes entirely from the \( \pi \) mechanism.

### 3.5 Through-space Coupling

In some molecules anomalously large coupling constants are observed between two nuclei separated many bonds away but spatially in close proximity to each other. This type of coupling is thought to arise from nonbonding or van der Waals interaction of electron orbitals of two nuclei and is termed “through-space” coupling. It should be noted that there is some danger of confusing this term with the direct magnetic dipole–dipole interaction between two nuclei because the latter is also a through-space interaction.

Through-space coupling has been reported for spatially proximate pairs of nuclei of various types, including \( \text{\(^1\text{H}==\text{F}\)} \), \( \text{\(^1\text{H}==\text{F}\)} \), \( \text{\(^1\text{H}==\text{F}\)} \), \( \text{\(^1\text{H}==\text{F}\)} \), \( \text{\(^1\text{H}==\text{F}\)} \), etc. In earlier days there has been some skepticism and dispute over the origin and existence of this type of coupling but numerous examples provide convincing evidence in favor of it.\(^{35}\)

A semiempirical estimation of through-space (H, H) coupling is often made on the basis of Equation (33):

\[
J_{\text{AB}}^{\text{through-space}} = \text{constant } S_A(0)^2 S_B(0)^2 S_{AB}^2
\]

(33)

where \( S_{AB} \) is the overlap integral between the valence s-orbitals of atoms A and B and the constant is experimentally determined. However, Equation (33) does not seem to be suitable for estimating the through-space coupling constants involving \( \text{\(^1\text{F}\)} \) for which the overlap of lone-pair p-orbitals is expected to make appreciable contributions.

Experimental studies have shown that through-space FF coupling changes very steeply with distance between the coupled fluorine nuclei. In an interesting study\(^{33,34}\) that involves derivatives of 1,8-difluoronaphthalene (9) and 5,6-difluoroacenaphthalene (10) with various peri substituents serving to perturb the F–F distance in predictable ways it has been found that experimentally measured \( J_{\text{FF}} \) (in Hz) can be correlated with the F–F distance, \( d_{\text{FF}} \) (in nm), through Equation (34):

\[
J_{\text{FF}} = (9.65 \times 10^5) \exp(-3.78d_{\text{FF}})
\]

(34)

Such an excellent correlation also supports the existence of the through-space mechanism. Thus, in general, it will be more appropriate to write down \( J \) as a sum of through-bond and through-space components, as shown in Equation (35), although it is not easy to dissect the observed coupling constant into each component:

\[
J = J(\text{through-bond}) + J(\text{through-space})
\]

(35)

### 4 Measurement of Scalar Spin Coupling Constants

A group of nuclear spins mutually coupled through scalar couplings comprises a spin system whose NMR spectrum shows a characteristic pattern of spectral splitting depending on the relative magnitude of chemical shifts and spin–spin coupling constants of involved spins. By observing and analyzing such a splitting pattern one can, in principle, extract information regarding the chemical shifts and spin–spin coupling constants for the given spin system. In practice, however, it is by no means trivial to extract all the relevant coupling parameters from overly crowded and overlapped spectra and to this end numerous ideas were contrived and applied in both one-dimensional and two-dimensional NMR spectroscopy. Both homonuclear and heteronuclear coupling constants for various spin systems have been successfully measured and correlated with electronic environments in many different kinds of molecules and the results are now tabulated in many standard NMR references. One can normally look up these tabulated data to gain information about the electronic structure of the molecules of interest with the aid of some semiempirical knowledge as explained in the previous section.

To be more specific, let us consider a spin system consisting of two coupled spins of \( I = \frac{1}{2} \) in the liquid state. For this spin system the spin Hamiltonian, expressed in
frequency units, may be written as shown in Equation (36)
\[
k^{-1}H = v_1 I_{1z} + v_2 I_{2z} + J \mathbf{I}_1 \cdot \mathbf{I}_2
\]
(36)
where \(v_1\) and \(v_2\) are the resonance frequencies of the two spins 1 and 2 (with respect to the observing radiofrequency (RF) carrier frequency) and \(J\) is the scalar coupling constant.

By diagonalizing the Hamiltonian matrix formed by the basis set of product functions \(|\alpha\alpha\rangle, |\alpha\beta\rangle, |\beta\alpha\rangle, \) and \(|\beta\beta\rangle\) we can find the eigenfunctions and eigenvalues for this two-spin system and the corresponding relative absorption line intensities can be found by evaluating \(|\langle i|F^+|i\rangle|^2\) for every possible transition between two eigenstates \(i\) and \(j\) where \(F^+ \equiv (I_{1x} + iI_{1y}) + (I_{2x} + iI_{2y})\). The resulting theoretical spectrum is shown in Figure 4. We see from Figure 4 that the appearance of the NMR spectrum for this spin system varies widely depending on the magnitude of \(|J|\) relative to the chemical shift difference \(|v_1 - v_2|\). In the limit \(|J|/|v_1 - v_2| \ll 1\) each resonance line for two spins appears as a doublet centered at the respective chemical shift frequency with equal intensity and interval \(|J|\). In this case the system is said to display a first-order spectrum and be weakly coupled. A weakly coupled two-spin system is conventionally denoted as \(AX\). Why the name first-order? In order to understand the reason we rewrite the scalar coupling term in Equation (36) as Equation (37):
\[
J \mathbf{I}_1 \cdot \mathbf{I}_2 = J[I_{1z}I_{2z} + \frac{1}{2}(I_{1x}^2 + I_{1y}^2 + I_{2x}^2 + I_{2y}^2)]
\]
(37)
where \(I^+\) and \(I^-\) stand, as explained in the standard textbooks on quantum mechanics, for the shifting operators for nuclear spin angular momentum \(I\). The first term on the right-hand side of Equation (37) gives the first-order correction to the unperturbed system consisting of two noncoupled \(I = \frac{1}{2}\) spins while the second term makes the second- or higher order contributions only. In other words, if we approximate the whole scalar coupling term \(J \mathbf{I}_1 \cdot \mathbf{I}_2\) by the first term \(J I_{1z}I_{2z}\), only, we would obtain the spectrum corresponding to the limit \(|J|/|v_1 - v_2| \ll 1\).

If \(|J|\) is comparable with \(|v_1 - v_2|\) in magnitude, the outer line in a doublet is always weaker than its inner line and an \(AB\)-type spectrum will result. In this case the second term in Equation (37) makes a significant contribution and the two spins are said to be strongly coupled. That is, when we describe a strongly coupled spin system, we have to keep the entire term in Equation (37).

Strongly coupled or not, the separation between the inner line and the outer one in a doublet is equal to \(|J|\) in frequency units. Unlike the coupling constant, however, in the case of an \(AB\)-type spectrum the chemical shift difference must not be read off as the separation between the respective midpoints of two doublets as is usually done in the case of an \(AX\) spectrum. Instead, it must be evaluated from the fact that \(\Delta\), the separation between the outer line of one spin and the inner line of the other, and \(J\) are related through the relation shown in Equation (38):
\[
\Delta = \sqrt{(v_1 - v_2)^2 + J^2}
\]
(38)
However, in the \(AB\) and/or \(AX\) system the sign of \(v_1 - v_2\) and \(J\) cannot be determined from the observed spectrum alone because its NMR spectrum is symmetrical with respect to the change of signs of these parameters. To determine their signs we need an extra source of information.

When the chemical shifts of the two spins 1 and 2 are exactly equal, we see from Figure 4 that splitting
disappears. It is generally true even for a multinuclear system that, if all the magnetic nuclei present have the same chemical shift, scalar couplings are inoperative in causing splitting.

In a heteronuclear two-spin system where two nuclei are of different kinds, as in the case of \(^1H\) and \(^13C\), the chemical shift difference is usually very large compared with \(|J|\) and the system can safely be regarded as an AX system. In a homonuclear spin system there is no such guarantee. Even in this case, however, we can speak of an AX system in the presence of strong static field \(B_0\) because the chemical shift difference, expressed in frequency units, increases with increasing field strength and at very high field it can dominate \(|J|\) which is influenced very little by \(B_0\).

Another interesting spin system relevant to the scalar coupling is an \(A_2B\) system which consists of two magnetically equivalent spins denoted by \(A\) and a third spin, denoted by \(B\), strongly coupled to them. (Two spins are said to be magnetically equivalent if they have the same chemical shifts and their coupling constants with all other magnetic nuclei present in the spin system are equal.) The spin Hamiltonian for this system may be written as shown in Equation (39):

\[
h^{-1}H = v_A I_{A1z} + v_A I_{A2z} + J_{A1A2} I_{A1} \cdot I_{A2} + J_{AB} (I_{A1} \cdot I_B + I_{A2} \cdot I_B) \tag{39}
\]

where we have noted that, since the two spins \(A_1\) and \(A_2\) are magnetically equivalent, \(v_{A1} = v_{A2} = v_A\) and \(J_{A1B} = J_{A2B} = J_{AB}\). The corresponding Hamiltonian matrix can be factored to four \(1 \times 1\) and two \(2 \times 2\) matrices if we choose a basis set complying with the fact that \(H\) is invariant with respect to the exchange of \(A_1\) and \(A_2\) and commutes with the operator \(I_{A1z} + I_{A2z} + I_{Bz}\). Theoretically simulated spectra for this spin system are shown in Figure 5 for a set of \(|v_A - v_B|/|J_{AB}|\) values. From this spectrum \(v_A - v_B\) and \(|J_{AB}|\) can be determined from the observed line positions but the sign of \(J_{AB}\) still remains unknown. Note in this case, too, that the scalar spin coupling between two magnetically equivalent nuclei \(A_1\) and \(A_2\) has no bearing on the appearance of spectra, whence no information on the \(J\) coupling between magnetically equivalent spins can be obtained. It is generally true that the scalar couplings among magnetically equivalent nuclei cannot result in any spectral change for larger spin systems, either, because the sum of magnetically equivalent spin operators \(I_k\) commutes with the sum of the scalar coupling terms among these spins.

The next simplest and frequently encountered spin system is an \(ABX\) system which consists of two strongly coupled nuclei and a third nucleus which is coupled weakly to the former. For this system the spin Hamiltonian may be written as shown in Equation (40):

\[
h^{-1}H = v_A I_{Az} + v_B I_{Bz} + v_X I_{Xz} + J_{AB} I_A \cdot I_B + J_{AX} I_{Ax} I_{Xz} + J_{BX} I_{Bx} I_{Xz} \tag{40}
\]

If we form the energy matrix by employing the basis set of product functions \(|\alpha \alpha \beta \alpha \alpha X\rangle, |\alpha \alpha \alpha \beta \alpha X\rangle, |\beta \alpha \alpha \beta \alpha X\rangle\), etc., the matrix elements between two different spin states of \(X\) will be vanishing. Therefore, we may treat the \(AB\) part of the \(ABX\) spectrum as a superposition of two \(AB\) spectra centered at different positions,

![Figure 5 Stick plot for theoretical spectrum for \(A_2B\) spin system for various values of \(J/b\) (\(b \equiv |v_A - v_B|\)).](image-url)
AB starts with identifying two sets of from transitions due to X region may be shown to consist of four lines originating JAB changing the sign of AB the case of an between the center of two quartets no way of knowing whether entire spectrum itself, unchanged, which means we have NMR.

Depending on the signs and magnitudes of J_{AX} and J_{BX}, the spectral feature varies so widely that sometimes one is easily misled to believe that it arises from a different spin system other than ABX. One such example may be seen in the case when J_{AX} = 0, J_{BX} ≠ 0 with A and B strongly coupled. In the first-order interpretation one may expect that the X region consists merely of a doublet arising from coupling with B spin. In the actual ABX spectra the X spin signal usually shows additional splittings due to the presence of A to which it is not actually coupled. Musher and Corey\(^{35}\) referred to this ghostly coupling as virtual coupling. However, this concept was introduced merely for convenience of understanding the spectra in the first-order approximation and should not be regarded as real. Another baffling example of ABX spectra is the case where v_A ≈ v_B. As v_A approaches v_B, the spectral appearance changes drastically and when v_A = v_B the AB region appears to be simply a doublet while the X region is a 1:2:1 triplet, as shown in Figure 7. Although there can be other weak lines as shown in Figure 7, they are normally lost in noise. This deceptively simple spectrum may mistakenly be interpreted as that of an A_2X spin system with only one J_{AX} coupling constant present if one does not realize that this is a special case of ABX (actually AAX, since the chemical shifts of A and B are equal. In this case the two spins A and B are not magnetically equivalent although their chemical shifts are the same, hence being written as AA instead of A_2). The apparent coupling constants which can be read off from splittings seen in the doublet or triplet are actually an average of two coupling constants J_{AX} and J_{BX}. For example, the proton resonance spectrum of 2,5-dichloronitrobenzene taken at 60 MHz\(^{36}\) actually consists of a doublet and a triplet which one may be tempted to interpret as arising from an A_2X spin system with J_{HH}(meta) = J_{HH}(para) = 1.6 Hz. However, it is found that, if we take the spectrum of the same sample at, say, 200 MHz, a typical ABX-type spectrum results, giving J_{HH}(meta) ≈ 3 Hz and J_{HH}(para) ≈ 0 Hz. Such deceptively simple spectra are widespread and not limited to ABX systems. We can easily beat these deceptively simple spectra by recording them on a spectrometer operating at higher fields because the splitting pattern of a true A_2X will not depend on the strength of the applied magnetic field.

The easiest case for a three-spin system is to interpret the AMX-type spectra. In this case the NMR absorption line for a spin, say A, is split first by M, interspaced by J_{AM}, and then further by the second coupling partner X, interspaced by J_{AX}, all with equal intensities. In particular, if all the spins involved have I = ½ and the two coupling constants J_{AM} and J_{AX} are equal, that is, in the case of the AX_2 spin system, two of the split lines will overlap, giving the intensity ratio 1:2:1. This trend may be extended
to a multiplet spin system. For example, in the case of the \( AX_3 \) spin system the \( A \) spectrum will consist of four lines interspaced by \( J_{AX} \) with the intensity ratio 1:3:3:1. Most generally, in the case of \( AX_n \) we will have the \( A \) spectrum consisting of \( n + 1 \) lines with the intensity ratio of \( \left( \begin{array}{c} n \\ 0 \end{array} \right) : \left( \begin{array}{c} n \\ 1 \end{array} \right) : \left( \begin{array}{c} n \\ 2 \end{array} \right) : \cdots : \left( \begin{array}{c} n \\ n - 1 \end{array} \right) : \left( \begin{array}{c} n \\ n \end{array} \right) \).

A most general \( ABC \)-type spectrum for a strongly coupled three-spin system cannot be treated exactly, but with the aid of a computer it can readily be interpreted numerically, yielding information about the magnitudes of three coupling constants \( J_{AB}, J_{AC}, \) and \( J_{AB} \). For a higher spin system it is in general impossible to treat the problem analytically except for a few cases. However, numerical solutions even for the complicated multiplet systems are available and have been implemented on modern NMR spectrometers. If all the lines for a given spin system are observed with good resolution, it is not difficult to extract information on the chemical shift of each constituent spin as well as the internuclear spin coupling constants, except for relative signs of these parameters, by analyzing the observed spectra as described above. In reality, however, for large molecules with many magnetic nuclei the one-dimensional NMR spectra are usually so crowded with many lines arising from nuclei of different chemical shifts as well as scalar spin couplings between them (and sometimes with considerable numbers of lines overlapped and weaker lines buried under the stronger ones) over the observed range of frequency that it is by no means easy to interpret and assign the spectral lines following the standard procedure described above. Moreover, in some cases it may not be clear which spin is scalar-coupled to which. To help ease such difficulties, in one-dimensional NMR one may employ double resonance techniques such as spin decoupling, spin tickling, internuclear double resonance (INDOR), pseudo-INDOR, selective population transfer, etc. Among these, spin decoupling is the most frequently used technique for reducing the spectral complexities in which one irradiates a specific nucleus with the second RF field at its resonance frequency. Upon irradiation the multiplet structures arising from coupling with the irradiated nucleus collapse, which results in considerable reduction of the complexity of the observed spectra. However, in this case the information on the coupling constant between the spin of interest and that irradiated is also lost. The procedure of irradiating the spins one by one employed in one-dimensional NMR is usually very cumbersome (and sometimes not possible), in which case the two-dimensional techniques such as correlation spectroscopy (COSY), two-dimensional \( J \)-resolved spectroscopy, etc. are more advantageous.

When the couplings between two different kinds of nuclei, such as \(^1\text{H}\) and \(^{13}\text{C}\) (that is, heteronuclear couplings), become a nuisance, one may employ the broadband decoupling technique in which the entire chemical shift range for one kind of coupling spin is irradiated with sufficient RF power. In this case the heteronuclear coupling information is completely lost, but homonuclear couplings can survive to give visible splitting as in the case of incredible natural abundance double quantum transfer experiment (INADEQUATE) spectra of \(^{13}\text{C}-^{13}\text{C}\) coupling obtained under broadband \(^1\text{H}\) decoupling. When the natural abundance of a coupling partner is so low that splitting caused by scalar spin coupling is not readily observed, one may employ such intensity enhancement techniques as insensitive nuclei enhanced by polarization transfer (INEPT). These and other techniques (\(\beta\)-COSY, E-COSY, etc.) may also be used to find the relative signs of various scalar coupling constants.

For some reasons (chemical exchange, quadrupolar relaxation, etc.) the scalar spin coupling expressed in the form of Equation (1) can be modulated randomly in time. In the case of chemical exchange one of the coupled spins may jump over different sites making the coupling constant \( J \) modulated. This kind of modulation can cause the scalar relaxation of the first kind. On the other hand, when one of the two coupled nuclei has its own strong relaxation mechanism such as quadrupolar relaxation, the scalar coupling is responsible for the scalar relaxation of the second kind. When one of the coupled spins, say \( S \), relaxes fast (that is, its spin–lattice relaxation time is short compared with \( 1/J \)), we can observe only a single line for the other spin, say \( I \), instead of the expected multiplet. In this case we cannot measure the coupling constant \( J \) between two spins \( I \) and \( S \). However, even in this case by making use of the relaxation data for two coupled spins we can estimate \( J \).\(^{37}\)

Solid-state nuclear magnetic resonance (NMR) spectroscopy is a powerful analytical technique with a wide range of applications in chemistry, biochemistry and materials science. Solid-state NMR is amenable to studies of molecular systems that are not suitable either for liquid-state NMR because of insolubility or for single-crystal diffraction techniques because of poor crystallinity. Therefore, solid-state NMR provides a natural connection between liquid-state NMR and single-crystal diffraction techniques. Furthermore, solid-state NMR is the best way of studying the anisotropic nature of nuclear magnetic properties, thus potentially yielding more complete information about molecular structure and chemical bonding.

This article provides an overview of the fundamental principles of solid-state NMR with selected examples of chemical applications. Emphasis is placed on the fundamental information and practical aspects of solid-state multinuclear NMR experiments for the following spin-1/2 nuclei: $^{15}$N, $^{29}$Si, $^{31}$P, $^{77}$Se, $^{113}$Cd, $^{199}$Hg, $^{117}$Sn, $^{195}$Pt, $^{207}$Pb, $^{57}$Fe, $^{89}$Y, $^{109}$Ag and $^{183}$W. A brief introduction to the second-order quadrupolar effect on spin-1/2 NMR spectra is also provided.

1 INTRODUCTION
Solid-state NMR spectroscopy is a powerful analytical technique with a wide range of applications in chemistry, biochemistry and materials science. Over the past 20 years, the advances in both NMR methodology and instrumentation have made equally important impacts on the development of the field. Today, it is generally accepted that solid-state NMR is applicable to a great variety of chemical and biological systems. One unique feature of solid-state NMR is that the method provides a natural connection between liquid-state NMR and diffraction techniques. The rapid expansion in chemical applications of solid-state NMR has been brought about for several reasons. First, the technological improvement of NMR spectrometers in the past 20 years has made solid-state NMR experiments routine. Second, there is potentially more information in solid-state NMR spectra. Third, NMR parameters such as the chemical shift tensor and the dipolar coupling constant are influenced only by the short-range environment around the nucleus of interest. Therefore, NMR is amenable to studies of chemical systems that cannot be obtained in crystalline form, e.g. semicrystalline and amorphous polymers. For these systems, single-crystal diffraction techniques are difficult to apply. Finally, many chemical systems such as cross-linked polymers and ceramics are insoluble in common solvents and hence are not suitable for solution NMR study.

In this article, we describe the basic principles of solid-state NMR spectroscopy and some specific applications in chemistry. We focus on NMR studies of spin-1/2 nuclei other than $^{13}$C and $^1$H. This article is not intended to be a literature review, which is neither necessary nor possible within the limited space. Instead, the article will provide readers with an overview of the fundamental principles of solid-state NMR and some selected examples of applications. Emphasis will be placed on the basic information about solid-state multinuclear NMR experiments and discussions about specific applications will be kept brief. For more detailed information about solid-state NMR, readers are referred to several excellent monographs. (1–10)

Research in multinuclear solid-state NMR spectroscopy is also periodically reviewed in the *Specialist Periodical Reports on NMR* published by the Royal Society of Chemistry, *Annual Reports on NMR Spectroscopy*, *NMR: Basic Principles and Progress*, *Progress in NMR Spectroscopy*, *Magnetic Resonance Review* and *Advances in Magnetic Resonance*. Another source of general information about NMR is the recently published *Encyclopedia of Nuclear Magnetic Resonance*. The large eight volumes cover almost all aspects of NMR and contain many excellent articles about solid-state NMR applications and historical accounts of technique development. Finally, the review article by Sebald, covering the literature up to 1993, also contains useful technical details and chemical applications of solid-state NMR of less common spin-$\frac{1}{2}$ nuclei.

Table 1 gives nuclear properties and reference samples for selected spin-$\frac{1}{2}$ nuclei.

2 BASIC PRINCIPLES AND TECHNIQUES

2.1 Nuclear Spin Hamiltonians

NMR spectroscopy, like all other spectroscopic techniques, is concerned with the study of a particular set of energy levels via the interaction between electromagnetic radiation and matter. More precisely, NMR spectroscopy deals with energy levels involving nuclear spins in the presence of a strong, static magnetic field. The electromagnetic radiation employed in NMR lies in the range of radiofrequency (RF), hence NMR spectroscopy is historically known as RF spectroscopy.

Generally, one can treat the nuclear spin system as an isolated system. That is, it is only necessary to consider a reduced-spin Hamiltonian rather than a total Hamiltonian describing the entire molecular system. Interactions of the nuclear spin system under observation with all other degrees of freedom including all possible time-dependent random interactions between the nuclear spins and environment are ascribed to the “lattice”. Interactions between nuclear spins and the lattice are important in understanding various NMR relaxation phenomena, but this article is not concerned with NMR relaxation phenomena.

For nuclear spin systems containing only spin-$\frac{1}{2}$ nuclei, the following four nuclear spin interactions have to be considered for diamagnetic solids: (i) the nuclear Zeeman interaction, (ii) the chemical shielding interaction, (iii) the direct magnetic dipole–dipole interaction and (iv) the indirect electron-mediated spin–spin interaction or the $J$ interaction.

2.1.1 The Nuclear Zeeman Interaction

The basic and strongest interaction in NMR is the interaction between a nuclear magnetic dipole moment, $\mu$, and an external magnetic field, $B_0$, namely the nuclear Zeeman interaction. A nuclear magnetic dipole moment is the intrinsic property of a nucleus and is related to the total nuclear spin angular momentum, $\hbar I$, by
Equation (1):

\[ \mathbf{\mu} = \gamma \left( \frac{\hbar}{2\pi} I \right) \]  

where \( \gamma \) is the magnetogyric ratio and \( \hbar \) is Planck’s constant. The magnitude of the nuclear spin angular momentum is given by \( h(I(I + 1))^{\frac{1}{2}} \), where \( I \) is either an integer or half-integer. If the direction of the external magnetic field is defined as the \( z \) direction, the nuclear Zeeman Hamiltonian can be written as Equation (2):

\[ h^{-1}H_z = -\mathbf{\mu} \cdot \mathbf{B}_0 = - \frac{\gamma}{2\pi} \mathbf{I} \cdot \mathbf{B}_0 = - \frac{\gamma}{2\pi} B_0 m_Z \]  

where \( m_Z \) is the \( z \) component of the nuclear spin angular momentum \( (m_Z = I, I - 1, \ldots, -I) \). For a nucleus with \( I = \frac{1}{2} \), \( m_Z \) takes values of \( +\frac{1}{2} \) and \( -\frac{1}{2} \), leading to a two-level system. The two spin states are usually denoted \( |\uparrow\rangle (m_Z = +\frac{1}{2}) \) and \( |\downarrow\rangle (m_Z = -\frac{1}{2}) \), or as the “up” and “down” spin states, respectively. The energy separation between the two nuclear spin states is given by Equation (3):

\[ \Delta E = \gamma \left( \frac{\hbar}{2\pi} \right) B_0 \]  

In the presence of electromagnetic radiation, transitions between the two nuclear spin states may be induced if the quanta of applied radiation satisfy the condition in Equation (4):

\[ \nu_0 = \frac{\gamma}{2\pi} B_0 \]  

where \( \nu_0 \) is known as the Larmor frequency in units of \( s^{-1} \) (hertz or Hz). The magnitude of the nuclear Zeeman interaction is usually expressed by the Larmor frequency. It is clear from Equation (4) that the nuclear Zeeman interaction depends on the magnetogyric ratio of the nuclear species under observation and the strength of the applied magnetic field, \( B_0 \). For protons, typical nuclear Zeeman interactions in the magnetic field of modern NMR spectrometers \( (B_0 = 2.35–17.62 \text{T}) \) are in the range 100–750 MHz. The nuclear Zeeman interaction is extremely weak compared with interactions studied by other spectroscopic techniques. For example, the nuclear Zeeman interaction energy of protons in a magnetic field of 14.10 T corresponds to a thermal energy of 28.8 mK.

In a macroscopic sample, one deals with a large number of nuclear spins \( (10^{18}–10^{23}) \). At thermal equilibrium the population of nuclear spins at \( |\uparrow\rangle \) and \( |\downarrow\rangle \) states is given by the Boltzmann distribution (Equation 5):

\[ \frac{n_\uparrow}{n_\downarrow} = \exp \left( \frac{-\Delta E}{kT} \right) = \exp \left( -\frac{\gamma(\hbar/2\pi)B_0}{kT} \right) \]  

Since the nuclear Zeeman interaction is extremely weak, it results in an extremely small population difference between \( |\uparrow\rangle \) and \( |\downarrow\rangle \) states. For instance, \( n_\uparrow/n_\downarrow = 0.99996 \) for \(^1\text{H}\) at 300 K in a magnetic field of 14.10 T. This makes NMR spectroscopy a rather insensitive spectroscopic technique in the sense that a relatively large number of nuclear spins are required in order to make NMR signals detectable. However, the extremely weak nuclear spin interactions make it possible for atomic nuclei to become a microscopic probe extremely sensitive to subtle variations in molecular and electronic structures.

It is clear from Equation (2) that the nuclear Zeeman interaction is of no explicit interest for chemists, since all nuclei of a given isotope would absorb RF radiations at the same frequency. If the nuclear Zeeman interaction were the only nuclear spin interaction present, NMR would be of no use to chemists. However, the nuclear Zeeman interaction is analogous to the carrier wave in radio broadcasting, without which all beautiful “music” arising from other subtle nuclear spin interactions could not be enjoyed.

2.1.2 The Chemical Shielding Interaction

In the above discussion of nuclear Zeeman interactions, one in fact deals with a bare nucleus; however, chemists are most interested in molecules. This implies that one must consider nuclei surrounded by electrons. Therefore, interactions among nuclei, electrons and an external magnetic field become important. It is well known that electron circulating motions induced by an external magnetic field will generate a secondary magnetic field at the nucleus. Thus, a nucleus will generally experience a magnetic field slightly different from the applied field. This phenomenon is known as chemical shielding. The effective magnetic field at the nucleus can be written as Equation (6):

\[ B_{\text{eff}} = (1 - \sigma)B_0 \]  

where \( \sigma \) is a small, dimensionless quantity \( (\sigma \ll 1) \) called the chemical shielding constant.

It can be readily appreciated that, if the electronic environment at the nucleus deviates from spherical symmetry, the chemical shielding at the nucleus will depend on the orientation of the molecule with respect to the external magnetic field. In general, the chemical shielding property can be described by a second-rank tensor and the chemical shielding Hamiltonian can be written as Equation (7):

\[ h^{-1}H_{\text{CS}} = \mathbf{\mu} \cdot \sigma \cdot \mathbf{B}_0 \]
It is clear from Equation (7) that the chemical shielding introduces an additional magnetic field, \((\sigma_{zz}, \sigma_{xx}, \sigma_{yy})B_0\). Since \(\sigma \ll 1\), the effective field that a nucleus feels is still approximately along the \(B_0\) direction (i.e. the \(z\) direction). This is known as the secular approximation or truncation.\(^{(3)}\) Under this approximation, the chemical shielding Hamiltonian is rewritten as Equation (8):

\[
h^{-1}H_{CS} = \frac{\nu}{2\pi} \sigma_{zz} B_0 I_z
\]

(8)

Usually \(\sigma\) is a general \(3 \times 3\) matrix that can be separated into a symmetric and an antisymmetric matrix; however, the antisymmetric part does not contribute to \(\sigma_{zz}\) and therefore has no influence on NMR spectra under the secular approximation. The symmetric chemical shielding tensor can always be diagonalized and the three diagonal elements are called principal components of a chemical shielding tensor, denoted \(\sigma_{11}, \sigma_{22}\) and \(\sigma_{33}\) \((\sigma_{11} < \sigma_{22} < \sigma_{33})\). The transformation to fulfills such a diagonalization defines the orientation of a chemical shielding tensor with respect to the crystal axis system.

If the direction of the external magnetic field is described by directional cosines \((\cos X, \cos Y, \cos Z)\) in the principal axis system of a chemical shielding tensor, the observed NMR frequency can be written as Equation (9):

\[
v = v_0 [1 - (\sigma_{11} \cos^2 X + \sigma_{22} \cos^2 Y + \sigma_{33} \cos^2 Z)]
\]

(9)

Often one has a sample consisting of many small crystallites in the form of a powder. Therefore, the orientation of the crystallites is random with respect to the external magnetic field. This is equivalent to saying that the orientation of the external magnetic field is random in the principal axis system of the chemical shielding tensor for all crystallites. This leads to a distribution of NMR frequencies and the resultant NMR line shapes are called NMR powder line shapes or powder patterns. Typical powder patterns due to anisotropic chemical shielding are shown in Figure 1(a–c).

The magnitude of the chemical shielding interaction is much smaller than that of the nuclear Zeeman interaction. However, it is its weakness that makes the chemical shielding interaction the most important NMR interaction for chemists. Atomic nuclei are spatially localized and are extremely sensitive to the electronic environment around them. The energy difference between different NMR signals could be of the order of \(10^{-6} \text{ J mol}^{-1}\) ! It is this sensitivity, or perhaps resolution might be a better term, that leads to the many versatile chemical applications of NMR spectroscopy.

It should be mentioned that, in actual NMR experiments, one always measures NMR signals with respect to that of a reference. The difference between NMR signals due to the sample of interest and that of the reference is called the chemical shift, \(\delta\), and expressed in units of parts per million (ppm). The relationship between the observed chemical shift and the chemical shielding is given by Equation (10):

\[
\delta_{\text{sample}} = \frac{10^6 (w_{\text{sample}} - w_{\text{ref}})}{w_{\text{ref}}} \approx 10^6 (\sigma_{\text{ref}} - \sigma_{\text{sample}})
\]

(10)

Therefore, a chemical shielding tensor is also related to a chemical shift tensor. Once the absolute shielding for the NMR signal in a reference sample has been established, all chemical shift data for the same nuclear species can be easily converted to absolute chemical shielding.

The three principal components of a chemical shift tensor are sufficient to describe the anisotropic chemical shift; for convenience, three other quantities, known as the isotropic value, the span (\(\Omega\)) and the skew (\(\kappa\)) of a chemical shift tensor, are also used for describing chemical shift tensors.\(^{(13)}\) Their definitions are given in Equations (11–14):

\[
\sigma_{\text{iso}} = \frac{(\sigma_{11} + \sigma_{22} + \sigma_{33})}{3}
\]

(11)

\[
\delta_{\text{iso}} = \frac{(\delta_{11} + \delta_{22} + \delta_{33})}{3}
\]

(12)
The means of these quantities are clear in terms of the appearance of a powder pattern arising from anisotropic chemical shifts. The isotropic value defines the center of the powder pattern, the span describes the breadth of the powder pattern and the skew represents the asymmetry of the powder pattern. These conventions will be used throughout this article.

One of the advantages of solid-state NMR over solution NMR is the ability to measure the complete chemical shift tensor rather than its average (isotropic) value alone. Ideally, one prefers to study NMR signals of a single-crystal sample at different orientations with respect to the external magnetic field. From the variation of NMR signals as a function of the sample orientation, one can determine the orientation of a chemical shift tensor in the molecular frame of reference. If single crystals are unavailable, one can still obtain information on the three principal components of a chemical shift tensor from studying powder samples; but orientation information is unavailable. In some favorable situations, however, one can employ a technique known as dipolar NMR to powder samples and obtain information on both the magnitude and orientation of chemical shift tensors.\(^{14,15}\) Chemical shift tensors reported in the literature have been compiled by Duncan.\(^ {16}\)

### 2.1.3 The Direct Magnetic Dipole–Dipole Interaction

In the presence of a strong external magnetic field, the magnetic dipole moment associated with a nuclear spin angular momentum can be visualised as a tiny bar magnet, hence producing a magnetic field around it. Any nucleus that resides in the vicinity of this tiny bar magnet will experience its magnetic field, in addition to the much larger applied magnetic field.

The interaction between two tiny bar magnets can be described by a magnetic dipole–dipole interaction. The magnetic dipole–dipole interaction Hamiltonian can be readily derived from the classical expression and it has the following form (Equation 15):\(^ {11}\)

\[
H_{DD} = (A + B + C + D + E + F)R_{DD}
\]

where the various terms are defined in Equations (16–22):

\[
A = -I_{1z}I_{2z}(3\cos^2\theta - 1)
\]

\[
B = \frac{1}{4}(I_{1z}I_{2-} + I_{1-}I_{2+})(3\cos^2\theta - 1)
\]

\[
C = \frac{3}{4}(I_{1z}I_{2+} + I_{1+}I_{2-})\sin\theta \cos\theta \exp(\pm i\phi)
\]

\[
D = -\frac{3}{4}(I_{1z}I_{2-} + I_{1-}I_{2+})\sin\theta \cos\theta \exp(\mp i\phi)
\]

\[
E = -\frac{3}{8}I_{1+}I_{2+} \sin^2\theta \exp(-2i\phi)
\]

\[
F = -\frac{3}{8}I_{1-}I_{2-} \sin^2\theta \exp(2i\phi)
\]

\[
R_{DD} = \frac{\mu_0}{4\pi} \gamma_1\gamma_2 \left( \frac{h}{4\pi^2} \right) \left( \frac{1}{r^3} \right)
\]

The terms \(A–F\) are known as the “dipolar alphabet” and \(R_{DD}\) is the direct dipolar coupling constant. The angles \(\theta\) and \(\phi\) are defined in Figure 2(a). In the presence of a strong magnetic field along the \(z\) direction, the dipolar alphabet is truncated, so that only the \(A\) and \(B\) terms remain for homonuclear spin pairs (Equation 23):

\[
h^{-1}H_{DD} = (A + B)R_{DD}
\]

\[
= -\frac{3}{2}(3I_{1z}I_{2z} - I_{1}I_{2})R_{DD}
\]

It is worth mentioning, however, that the above truncation is valid only if the nuclear Zeeman interaction is much larger than any other interactions involving the nuclear spins. In the presence of other strong interactions, such as a quadrupole interaction, all other terms from \(C\) to \(F\) may be important.

Since the direct magnetic dipole–dipole interaction is axially symmetric and traceless, there is only one...
indirect interaction between two identical spin-$\frac{1}{2}$ nuclei is displayed in Figure 2(b).

It is readily seen that a direct magnetic dipole–dipole interaction depends on the magnetic moments of two interacting nuclei and their spatial separation. The magnitude of a dipolar interaction is expected to be large for nuclear species with a high magnetogyric ratio and also for nuclei with a close spatial separation. By studying a direct magnetic dipole–dipole interaction, valuable structural information can be deduced. For example, one of the pioneering experiments in the early stages of NMR spectroscopy was performed by Pake.\(^{(17)}\) He measured the dipolar interaction between each pair of hydrogen nuclei in the water molecules of hydration in gypsum crystals (CaSO$_4 \cdot$2H$_2$O), from which a $^1$H–$^1$H separation of 1.58 Å was obtained. As will be shown later, the dipolar interaction is the major source of information about molecular structure from solid-state NMR studies.

2.1.4 The Indirect Electron-mediated Spin–Spin Interaction

Another type of nuclear spin interaction in NMR is that between nuclear spins transmitted via intervening electrons, namely the $J$ interaction. In contrast to the direct magnetic dipole–dipole interaction, the $J$ interaction is indirect, since it involves nucleus–electron interactions. The $J$ interaction is more complicated than the three aforementioned nuclear spin interactions. In general, there are three mechanisms for an indirect spin–spin interaction: (i) the interaction between a nuclear spin and electron orbital angular momenta; (ii) the magnetic dipole–dipole interaction between a nuclear spin and electron spins; and (iii) the Fermi contact interaction which arises from the fact that the s-electrons have a nonzero probability of being found at the nucleus. Moreover, since the Hamiltonians describing the last two interactions do not commute, they do not have a common set of eigenfunctions. As a result, state mixing occurs between their corresponding eigenstates, leading to a cross-term that contributes to the indirect spin–spin interaction. More detailed discussion on $J$ interactions can be found in the literature.\(^{(18)}\)

The indirect spin–spin interaction Hamiltonian can be written as Equation (24):

$$h^{-1}H_J = I_1 \cdot J \cdot I_2$$  \hspace{1cm} (24)

Again, the presence of a strong magnetic field truncates the total Hamiltonian and the secular Hamiltonian becomes Equation (25):

$$h^{-1}H_J = J_{\text{iso}}I_1 \cdot I_2 + \frac{J_{zz} - J_{\text{iso}}}{2}(3I_1I_2z - I_1 \cdot I_2)$$
$$+ \frac{J_{yy} - J_{zz}}{2}(I_1I_2y - I_1J_2y)$$  \hspace{1cm} (25)

where $J_{\text{iso}}$ is the isotropic value of the $J$ tensor in frequency units. Often $J$ is assumed to be a symmetric tensor. Under these conditions, the last term in Equation (25) vanishes. Regardless, this latter term does not contribute to the NMR line position in first order. A more detailed discussion concerning the antisymmetric part of a $J$ tensor can be found in the literature.\(^{(2)}\) If a $J$ tensor is further assumed to be axially symmetric with the unique axis being coincident with the internuclear vector, one has Equation (26):

$$J_{zz} = \begin{pmatrix}
\cos \theta & 0 & \sin \theta \\
-\sin \theta & 0 & \cos \theta \\
\sin \theta & 0 & \cos \theta
\end{pmatrix}
\begin{pmatrix}
J_{\perp} & 0 & 0 \\
0 & J_{\perp} & 0 \\
0 & 0 & J_{||}
\end{pmatrix}
\begin{pmatrix}
\cos \theta & 0 & -\sin \theta \\
0 & 1 & 0 \\
\sin \theta & 0 & \cos \theta
\end{pmatrix}
\begin{pmatrix}
J_{\perp} \sin^2 \theta + J_1 \cos^2 \theta
\end{pmatrix}$$  \hspace{1cm} (26)

Substituting Equation (26) into Equation (25), one obtains the spin Hamiltonian due to a symmetric $J$ tensor (Equation 27):

$$h^{-1}H_J = J_{\text{iso}}I_1 \cdot I_2 + \frac{\Delta J}{3} \frac{3 \cos^2 \theta - 1}{2}(3I_1I_2z - I_1 \cdot I_2)$$  \hspace{1cm} (27)

where Equation (28)

$$\Delta J = J_{||} - J_{\perp}$$  \hspace{1cm} (28)

It is clear from Equations (23) and (27) that the spatial and spin dependence in the direct magnetic dipole–dipole and the $J$ interaction Hamiltonians are similar. Therefore, it is usually difficult to separate a $J$ tensor from a dipolar interaction tensor, that is, the experimental observable will be a combination of these two interactions. The experimental observable will be a simple quantity known as the effective dipolar coupling constant, $R_{\text{eff}}$ (Equation 29):

$$R_{\text{eff}} = R_{\text{DD}} - \frac{\Delta J}{3}$$  \hspace{1cm} (29)
Although numerous chemical applications have been made of the isotropic values of $J$ interactions, much less is known about the anisotropy in $J$ interactions. In fact, as long as the electronic environment at the nucleus deviates from spherical symmetry, the $J$ interaction must be anisotropic. This can be readily appreciated when considering the similarity between the chemical shielding and one of the mechanisms for $J$ interactions, the spin–orbital mechanism. In the case of chemical shielding, it is the external magnetic field causing unquenching of the electron orbital angular momentum, whereas in the case of $J$ interaction, it is the field generated by the nuclear magnetic dipole moment that introduces unquenching of the electron orbital angular momentum. Since the electronic environment is not spherically symmetric, the degree of such unquenching will depend on the orientation of the nuclear magnetic moment in the molecule under study. Note that the orientation of the nuclear magnetic moment for a spin-$\frac{1}{2}$ nucleus is always forced to align along the external magnetic field. Hence the magnitude of a $J$ interaction will depend on how the molecule orients itself with respect to the external magnetic field.

In general, it is difficult to measure $J$ tensors experimentally. To date, the most definite $J$-tensor measurements have been based on single-crystal NMR studies.\textsuperscript{(19–21)} There are also several cases where $J$ tensors have been determined from solid-state NMR studies of powder samples.\textsuperscript{(22–30)} It should be pointed out that the $1J({}^{31}P,{}^{31}P)$ tensors in tetraalkylphosphine disulfides,\textsuperscript{(31)} the often quoted examples for $J$ anisotropy, are proved to be nearly isotropic.\textsuperscript{(32)} Finally, information about $J$ tensors is also available from NMR studies of solute molecules dissolved in liquid crystalline solvents. Several $J$ tensors have been measured by this approach, e.g. $J(^{19}F,{}^{13}C)$\textsuperscript{(33)} and $J(^{199}Hg,{}^{13}C)$.\textsuperscript{(34)}

### 2.2 Experimental Solid-state Nuclear Magnetic Resonance Techniques

In the solid state, the absence of rapid molecular tumbling makes the observation of a high-resolution NMR spectrum very difficult. Usually it is helpful to make a distinction between an abundant spin system and a rare spin system, since the NMR techniques involved in the two situations are different. Abundant spins are most often $^1H$ and $^{19}F$ nuclei and rare spins are magnetically dilute nuclei such as $^{15}N$ and $^{29}Si$. In this article, we shall consider only solid-state NMR techniques for studying dilute spin-$\frac{1}{2}$ systems.

#### 2.2.1 High-power Abundant Spin Decoupling and Magic-angle Spinning

One major problem encountered in obtaining high-resolution NMR spectra for solids arises from the anisotropic nature of all nuclear spin interactions. Among the anisotropic interactions present in magnetically dilute spin systems, the heteronuclear dipole–dipole interaction between dilute and abundant spins usually gives rise to broad, featureless NMR line shapes, whereas other interactions may result in NMR line shapes with some specific features. Therefore, it is desirable to eliminate the heteronuclear dipolar interaction between dilute and abundant spins. This can be achieved by applying strong RF radiation at the resonance frequency for abundant spins. The strong on-resonance RF radiation rapidly changes the spin state of the abundant spins and leads to spin decoupling. Under such conditions, the $J$ interaction between abundant and dilute spins is also eliminated by spin decoupling. The resultant decoupled NMR spectra of the dilute spins will be determined solely by the chemical shielding. Although useful information can be extracted from such a decoupled NMR spectrum, spectral overlap usually limits its usage to nuclear systems consisting of only a small number of dilute spins.

In order to eliminate further the remaining anisotropic chemical shielding interaction, another technique known as magic-angle spinning (MAS)\textsuperscript{(35–37)} must be employed. The MAS technique involves high-speed sample rotation about an axis inclined $54'$ with respect to the external magnetic field. The rapid mechanical specimen rotation acts more-or-less like the molecular tumbling in isotropic liquids and results in solid-state NMR spectra consisting of sharp peaks. Typical sample spinning frequencies in modern NMR probes are below 35 kHz. If the sample rotation frequency is smaller than the frequency range that results from the anisotropic chemical shielding interaction, the central (isotropic) NMR peak will be flanked by a set of peaks with the separation between neighboring peaks being equal to the specimen rotation frequency. These peaks are known as the spinning sidebands. Only when the rotation frequency is much greater than the anisotropic interaction (in frequency units) will all the spinning sidebands have negligible intensities. Unfortunately, the CSA for magnetically dilute spins, especially for heavy elements, is usually very large, which leads to the presence of significant spinning sidebands.

As an example, Figure 3(a–d) shows several solid-state $^{31}P$ NMR spectra of NH$_4$H$_2$PO$_4$ under different conditions. It can be seen that without applying the abundant spin (proton) decoupling, the $^{31}P$ NMR spectrum shows a broad peak, which is due to both the anisotropic $^{31}P$ chemical shift and the heteronuclear dipolar coupling to protons (Figure 3a). When the proton decoupling is applied, the $^{31}P$ NMR spectrum becomes sharper and exhibits a typical powder pattern arising from the anisotropic chemical shift (Figure 3b). After combining MAS and high-power $^1H$ decoupling, the $^{31}P$ NMR
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 3 Solid-state $^3$P NMR spectra of NH$_4$H$_2$PO$_4$: (a) without $^1$H decoupling; (b) with high-power $^1$H decoupling; (c) high-power $^1$H decoupling and MAS at 1543 Hz; (d) high-power $^1$H decoupling and MAS at 4024 Hz.

spectra bear significantly higher resolution (Figure 3c and d).

2.2.2 Cross-polarization

The concept of cross-polarization (CP) was first proposed by Hartmann and Hahn.$^{[38]}$ They demonstrated that spin polarization transfer can occur between two dipolar coupled spin systems, $I$ and $S$, if the two systems are set into “thermal contact”. The condition for such a transfer is now termed the Hartmann–Hahn match condition: $\gamma_I B_{1I} = \gamma_S B_{1S}$, where $B_{1I}$ and $B_{1S}$ are the rotating frame RF field strength for $I$ and $S$, respectively. However, the CP experiment of Hartmann and Hahn did not find widespread applications in chemistry until a direct version of CP was introduced by Pines et al.,$^{[39,40]}$ who demonstrated that NMR signals of dilute spins can be enhanced by transferring magnetization from the abundant spins. This direct version of CP has become a standard technique in obtaining solid-state NMR spectra of dilute spins. The advantage of using CP is not only to enhance the NMR signals of dilute spins, but also to make the repetition time of the NMR experiment depend on the spin–lattice relaxation time of the abundant spins, which is often orders of magnitude shorter than that of the dilute spins. For instance, the $^{13}$C spin–lattice relaxation time in a crystalline alkane C$_{60}$H$_{122}$ is more than 1660 s.$^{[41]}$ To study directly $^{13}$C nuclei in this sample, one must wait for over 2 h between two subsequent $^{13}$C 90° pulses in order for the $^{13}$C spin system to return to thermal equilibrium! On the other hand, the $^1$H spin–lattice relaxation time for this sample is of the order of seconds. Hence the repetition time for the CP experiment is only a few seconds. It is these two factors that make solid-state NMR studies of dilute spins feasible. The combination of CP, MAS and high-power abundant spin decoupling, often denoted cross-polarization/magic-angle spinning (CPMAS), was first demonstrated by Schaefer and Stejskal in 1976.$^{[42]}$ Since then CPMAS has become a powerful analytical technique routinely used by chemists in studies of a wide range of chemical systems.

2.2.3 Single-crystal Nuclear Magnetic Resonance

As mentioned earlier, single-crystal NMR is the ultimate method for yielding complete information about the orientation of a chemical shift tensor or any spin interaction tensor in the molecular frame of reference. Unfortunately, single-crystal NMR experiments are unfamiliar to chemists. The difficulties of such experiments are twofold. First, it is often difficult to obtain a single-crystal sample that is large enough for NMR measurement (e.g. sides of 1 mm or greater). Second, single-crystal NMR experiments are time-consuming. This is because one must carry out the same measurement for many different sample orientations. In addition, the spin–lattice relaxation times are usually very long in single crystals, adding another twist to the difficult experiments. Details concerning single-crystal NMR spectral analysis can be found in the literature.$^{[43]}$

It should be noted that, as the single-crystal NMR probe development continues,$^{[44]}$ single-crystal NMR
SOLID-STATE NMR: SPIN-1/2 NUCLEI OTHER THAN C AND H

studies are expected to become more feasible. These types of studies are of fundamental importance since they yield complete information (both the magnitude and orientation) about nuclear spin interaction tensors, providing benchmark data for testing ab initio quantum chemical calculations.

2.2.4 Dipolar Recoupling: Molecular Structure Determination

One of the most important solid-state NMR advances in the last decade is the development of NMR techniques that can measure geometric distances between two atomic nuclei. Since the essence of such techniques is to reintroduce dipolar interactions to NMR spectra under MAS conditions, they are also known as dipolar recoupling techniques. Recent developments in this area have been reviewed by Griffin et al. and Garbow and Gullion. However, reliable distance measurements have been limited to isolated spin pairs; it is natural to expect new methodologies for dealing with multiple-spin systems. Interestingly enough, complementary techniques have also appeared recently which, rather than measuring internuclear distances, provide information about the torsion angle between intermolecular vectors. Of course, with various torsion-angle constraints known, it is also possible to derive molecular structure.

3 SOLID-STATE NUCLEAR MAGNETIC RESONANCE OF MAIN GROUP ELEMENTS

3.1 Nitrogen-15

There are two NMR-active stable nitrogen isotopes: $^{14}$N (spin = 1) and $^{15}$N (spin = $\frac{1}{2}$). The natural abundance of the $^{15}$N isotope is only 0.37%, which makes it an insensitive NMR nucleus at natural abundance. The magnetogyric ratio of $^{15}$N is also quite low: $\gamma = -2.712 \times 10^7$ rad T$^{-1}$ s$^{-1}$ (the $^{15}$N NMR frequency is usually the lowest frequency to which most commercial MAS probes can be tuned). Consequently, solid-state $^{15}$N NMR at natural abundance has been uncommon. Since $^{15}$N isotopically enriched material is readily available now, most of the solid-state $^{15}$N NMR studies deal with $^{15}$N-labeled compounds. In fact, researchers in the field of protein structure determination using solution NMR spectroscopy usually utilize uniformly $^{15}$N-labeled proteins which can be readily obtained by expression in bacteria grown on a medium with $^{15}$NH$_4$Cl. A similar trend is emerging in the area of solid-state $^{15}$N NMR studies of proteins and polypeptides.

The nitrogen chemical shift covers a range of approximately 1000 ppm. The primary external standard for $^{15}$N chemical shift referencing is the neat MeNO$_2$. Another common $^{15}$N chemical shift reference is liquid ammonia at 20°C, whose $^{15}$N NMR signal appears at $-380.4$ ppm with respect to that of MeNO$_2$. The only advantage of using liquid NH$_3$ as a reference is that its nitrogen nucleus is more shielded than most of the nitrogen nuclei in chemical compounds. As a result, nearly all the $^{15}$N chemical shifts are positive on the liquid NH$_3$ scale. Nevertheless, one should be careful about the actual $^{15}$N chemical shift scale used in the published reports. The absolute nitrogen shielding constant in neat MeNO$_2$ and liquid ammonia at 300 K is $-135.8$ and 244.6 ppm, respectively. In $^{15}$N CPMAS experiments, the set-up sample as well as the secondary reference is a solid sample of $^{15}$NH$_4$NO$_3$, which gives rise to an NMR signal at $-359$ ppm with respect to that of MeNO$_2$, or 23.8 ppm with respect to that of liquid ammonia.

Although the isotropic $^{15}$N chemical shifts are known for hundreds of compounds over the past 50 years, much less experimental information is available on $^{15}$N chemical shift tensors. The first $^{15}$N chemical shift tensor was reported by Gibby et al. in 1972. However, not until recently have considerable efforts been devoted to the systematic measurement of $^{15}$N chemical shift tensors. To date, $^{15}$N chemical shift tensors have been characterized in many important functional groups.

As mentioned earlier, solid-state NMR studies of single crystals, powder and oriented samples can yield information about chemical shift tensors. The first $^{15}$N chemical shift tensor for the peptide bond was fully characterized by single-crystal NMR. Using a dipolar NMR approach, Wasylshen et al. have measured $^{15}$N chemical shift tensors in the oxime, imine, azo, and nitroso fragments for powder samples. Using oriented samples, Cross et al. studied the conformation of $^{15}$N-labeled gramicidin A in an oriented phosphatidylethanol bilayer environment. The largest $^{15}$N CSA values are those found in nitroso compounds and their complexes with transition metals. For example, the $^{15}$N NMR spectrum of p-nitroso-N,N-dimethylaniline exhibits a remarkably large CSA: $\Omega = 1500$ ppm. Groombridge et al. also observed large $^{15}$N CSAs in Co(NO)(TPP). Recently, Oldfield et al. carried out extensive investigations on a series of nitrosoarene compounds and their complexes to heme proteins. They found that the orientation of the $^{15}$N chemical shift tensor in the metal complexes is similar to that of the free ligand, but the anisotropy changes drastically. Figure 4(a) and (b) shows the orientations of the two $^{15}$N chemical shift tensors in Fe(TPP)(Ph$^{15}$NO)-(1-methylimidazole) and...

Co(OEP)($^{15}$NO) according to the density functional theory (DFT) shielding calculations.

In the areas of organic and inorganic chemistry, there are also many useful applications of solid-state $^{15}$N NMR. A more comprehensive account for $^{15}$N NMR applications can be found in the literature.

3.2 Silicon-29

The natural abundance of $^{29}$Si is 4.7%. The $^{29}$Si chemical shift reference is TMS. The $^{29}$Si chemical shift range is small: approximately 150 ppm. Most of the $^{29}$Si chemical shift values are negative and typical $^{29}$Si CSAs are less than 300 ppm. The set-up sample for $^{29}$Si CPMAS experiments is the Q$_8$M$_8$ [Si$_8$O$_{20}$][Si(CH$_3$)$_3$]$_8$. The most important applications of solid-state $^{29}$Si NMR are in various areas of silicate science including zeolites and silicate glasses and in organosilicon chemistry. Reviews of solid-state $^{29}$Si NMR can be found in the literature.

Two-dimensional (2-D) $^{29}$Si MAS NMR techniques such as correlation spectroscopy (COSY) and incredible natural abundance double quantum transfer experiment (INADEQUATE) have been used to establish the lattice connectivity in zeolites and silicate glasses. Figure 5 shows the 2-D solid-state $^{29}$Si COSY spectrum of high-silica zeolite ZSM-12. The observation of seven $^{29}$Si NMR peaks with approximately equal intensities indicates that the asymmetric unit consists of seven crystallographically distinct Si sites with equal occupancies. From the 2-D spectrum, information about the $^{29}$Si framework connectivity can be unambiguously assigned from the cross peaks that connect different $^{29}$Si NMR signals.

3.3 Phosphorus-31

Phosphorus-31 is among the most sensitive NMR nuclei because of its favorable NMR properties: spin = 1/2, natural abundance = 100% and $\gamma = 10.841 \times 10^7$ rad T$^{-1}$ s$^{-1}$. In contrast to $^{15}$N, the $^{31}$P NMR frequency is usually the high-frequency end of commercial MAS probes. The $^{31}$P chemical shift standard is 85% aqueous H$_3$PO$_4$, which has an absolute shielding constant of $\sigma = 328.35$ ppm. The set-up sample for $^1$H-to-$^{31}$P CP experiments is solid ammonium dihydrogenphosphate, NH$_4$H$_2$PO$_4$. This compound is also used as a secondary reference for $^{31}$P chemical shifts. The $^{31}$P NMR signal of solid NH$_4$H$_2$PO$_4$ appears at 0.81 ppm with respect to that of 85% aqueous H$_3$PO$_4$. Typical $^{31}$P chemical shifts for organophosphorus compounds are within a range of 500 ppm. However, extreme deshielding has also been observed for the $^{31}$P nuclei in bridging phosphinidene complexes, $\delta = 900–1400$ ppm, and in terminal phosphido...
complexes, $\delta = 1000$–1300 ppm. On an absolute shielding scale, the $^{31}$P NMR signals of these complexes are approximately 600–1100 ppm more deshielded than that of a bare $^{31}$P nucleus!

The utility of solid-state $^{31}$P NMR in studying catalytic compounds was first recognized in the early 1980s. Now solid-state $^{31}$P NMR is a routine technique in inorganic chemistry and organometallic chemistry for identifying molecular structure, bonding and polymorphism in conjunction with the X-ray diffraction technique. Applications of $^{31}$P CPMAS NMR to organophosphorus compounds and metal–phosphine complexes have been reviewed. More advanced techniques including various 2-D NMR techniques such as $J$-resolved, COSY and dipolar recoupling have also been applied to solid metal–phosphine complexes and phosphates.

Phosphorus chemical shift tensors have been measured in a large number of compounds. Several examples containing terminal phosphorus atoms are given in Table 2. These complexes exhibit the largest $^{31}$P CSAs observed to date. As seen in Figure 6(b), the spinning sidebands cover a frequency range of 300 kHz at 7.45 T. It is noted from Table 2 that the most shielded components, $\delta_{33}$, for all the compounds listed are similar whereas the least shielded components, $\delta_{11}$, differ by more than 2000 ppm.

Despite a large body of experimental data, a complete understanding of $^{31}$P chemical shift tensors, especially their relationship to molecular structure and bonding, is still under development. It is noted that several single-crystal $^{31}$P NMR studies of metal–phosphorus complexes have appeared in the literature. These studies yield precise information about both the magnitude and orientation of the phosphorus chemical shift tensors, which can be used as benchmarks for testing ab initio chemical shielding calculations.

All chemical shifts are in ppm. $\text{NN}_3 = [\text{Me}_3\text{Si}\text{NCH}_2\text{CH}_2\text{N}]^+$. Solid-state $^{31}$P NMR has also been a rich source for new spectral phenomena. The most important example is the discovery and development of the rotational resonance ($R^2$) methodology. The $R^2$ phenomenon was first observed by Andrew et al. in the $^{31}$P MAS spectra of solid $\text{PCl}_5$. They noticed that significant line broadening occurs when the sample spinning frequency is matched with the isotropic chemical shift difference between the signals arising from $[\text{PCl}_4]^+$ and $[\text{PCl}_6]^–$. However, this interesting observation had gone unnoticed until almost 25 years later when Raleigh et al. demonstrated that it is possible to utilize $R^2$ to measure the distance between a pair of homonuclear spins in polycrystalline solids. Recent developments in this area have been reviewed. Other examples of new phenomena related to solid-state $^{31}$P NMR include the observations of $J$ tensors and $J$-recoupling phenomena.

3.4 Selenium-77

The selenium element has only one naturally occurring spin-$\frac{1}{2}$ nucleus, $^{77}$Se (7.58%). Solid-state $^{77}$Se NMR is not very difficult with modern NMR instrumentation. The $^{77}$Se chemical shift reference is $\text{Se}(\text{CH}_3)_2$ at $23°C$, $\delta = 0$ ppm. The $^{77}$Se chemical shift spans a range of 1600 ppm. Ammonium selenate, $(\text{NH}_4)_2\text{SeO}_4$, is often
used as a set-up sample for $^{77}$Se CPMAS experiments and also as a secondary reference sample, $\delta = 1040.2$ ppm.\(^{(91)}\)

The largest $^{77}$Se CSA so far observed from solid-state NMR experiments is that found in (NH$_4$)$_2$WS$_4$, $\Omega = 1500$ ppm.\(^{(92)}\) Several large $^{77}$Se CSAs of similar magnitude were also reported, e.g. $\Omega = 1105$ ppm in SeO$_2$Cl$^-$\(^{(93)}\) and $\Omega = 1261$ ppm in [Me$_2$NH]$_2$Hg(Se$_4$)$_2$.\(^{(93)}\)

It is also noted that, from a liquid-crystal $^{77}$Se NMR study of carbon diselenide, a remarkably large CSA was reported, $\Omega = 2210$ ppm.\(^{(94)}\) Although a large body of solution $^{77}$Se NMR data is available in the literature, solid-state $^{77}$Se NMR studies have been scarce, most being concerned with inorganic compounds and materials.\(^{(95)}\) Since Se compounds are also important in organic chemistry, solid-state $^{77}$Se NMR is expected to be useful in the study of organoselenium compounds.

**4 SOLID-STATE METAL NUCLEAR MAGNETIC RESONANCE**

**4.1 Cadmium-113 and Mercury-199**

Cadmium has two stable spin-$\frac{1}{2}$ isotopes, $^{111}$Cd (12.75%) and $^{113}$Cd (12.26%). Since the $^{113}$Cd nucleus exhibits a slightly larger $\gamma$ value than $^{111}$Cd, the former has a higher NMR sensitivity. Hence $^{113}$Cd is the nucleus of choice for studying cadmium. The $^{113}$Cd chemical shift reference is the $^{113}$Cd NMR signal of 0.1 M aqueous solution of Cd(NO$_3$)$_2$. The set-up sample for $^{113}$Cd CPMAS experiments is Cd(NO$_3$)$_2$ $\cdot$ 4H$_2$O, which is also used as a secondary reference sample, $\delta = -100$ ppm.\(^{(96)}\) The $^{113}$Cd chemical shift range is approximately 900 ppm and the largest $^{113}$Cd CSA so far reported is that found in the complex of 18-crown-6 and CdCl$_2$, $\Omega = 1100$ ppm.\(^{(97,98)}\)

Because of its reasonably high natural abundance and favorable NMR frequency, solid-state NMR of $^{113}$Cd is straightforward.

The initial impetus of $^{113}$Cd NMR studies includes the possibility of using this nucleus as a surrogate nuclear probe to calcium- and zinc-containing proteins.\(^{(99,100)}\)

In addition, since divalent group 12 metal ions are diamagnetic and have a closed-shell d$^{10}$ electronic structure, neither electron spin resonance (ESR) nor optical spectroscopy is applicable. In this respect, $^{113}$Cd NMR is a unique technique capable of providing useful information about the metal binding to proteins. To date $^{113}$Cd NMR has been well established as an effective probe to Cd-substituted metalloproteins. Applications of $^{113}$Cd NMR have been summarized by Summers\(^{(101)}\) and more recently by Coleman.\(^{(102)}\)

Several general trends concerning the $^{113}$Cd chemical shift have been observed: (a) oxygen ligands generate the most shielded cadmium environment; (b) sulfur ligands are the least shielded; and (c) nitrogen and halide ligands provide a shielding environment between the oxygen and sulfur limits. For example, in a study of cadmium thiocyanate complexes, Eichele and Wasilishen found an almost additive relationship between the $^{113}$Cd chemical shift and the number of S-bonded thiocyanate ligands.\(^{(103)}\)

As shown in Figure 7, replacement of an N-bonded thiocyanate ligand by an S-bonded ligand causes an average $^{113}$Cd NMR signal shift of 38 ppm in the direction of deshielding.

In order to understand fully $^{113}$Cd chemical shifts, considerable efforts have been devoted to the measurement of $^{113}$Cd chemical shift tensors. In the last two decades, a large number of $^{113}$Cd chemical shift tensors have been characterized using both MAS and single-crystal NMR techniques.\(^{(104)}\) A good example illustrating why it is important to study the full chemical shift tensor rather than the isotropic chemical shift alone was given by Jakobsen et al.\(^{(104)}\) in the study of the meso-TPP of cadmium (Cd-TPP) and its pyridyl adduct (Py-Cd-TPP). The isotropic $^{113}$Cd chemical shift difference between the two compounds is only 33 ppm, making it difficult to distinguish between the two binding modes based on the observed isotropic chemical shifts alone. However, as seen in Figure 8, the two $^{113}$Cd chemical shift tensors are remarkably different: $\Omega = 341$ and 105 ppm for Cd-TPP and Py-Cd-TPP, respectively. It is clear that the pyridyl ligation causes opposite shielding changes in the individual tensor components, which essentially cancel the change in the isotropic chemical shift. There are many examples of this kind that emphasize the rich information from studying chemical shift tensors.

Unlike $^{113}$Cd NMR, solid-state $^{199}$Hg NMR is less common. This is mainly because Hg compounds often exhibit very large CSAs, especially in linear Hg compounds. For example, liquid-crystal NMR studies showed that the $^{199}$Hg CSA in Me$_2$Hg is $\Omega = 7475 \pm 80$ ppm.\(^{(105)}\) This value corresponds to a frequency range of 536 kHz at 9.4 T. The $^{199}$Hg chemical shift spans a range of 5000 ppm.
any Hg compound. dimethylmercury, one must take precautions in handling set-up sample as well as a secondary reference. Although been studied by solid-state199Hg NMR.

The commonly accepted 199Hg chemical shift reference is neat dimethylmercury, δ = 0 ppm (Caution! this compound is highly toxic). As a result of the recent tragic death of a chemist from dimethylmercury poisoning, attention has been drawn to using either a safer standard or an alternative approach for 199Hg NMR referencing. The suggested alternative approach is to first measure the 1H NMR frequency at 0 ppm, and to calculate the 199Hg frequency at 0 ppm using the conversion factor of 0.17910323. In the solid-state 199Hg NMR community, researchers always use a solid sample as a set-up sample as well as a secondary reference. Although solid Hg compounds are far less hazardous than neat dimethylmercury, one must take precautions in handling any Hg compound.

The originally proposed set-up sample for 199Hg CPMAS experiments was Hg(CH3COO)2, δ = −2497 ppm. However, this compound is far from being an ideal set-up sample since it has a very large value of 199Hg CSA (Ω = 1826 ppm) and a long 1H spin–lattice relaxation time (T1 = 25 s). These disadvantages render the set-up procedure time-consuming. Two new compounds have recently been proposed as set-up samples for 199Hg CPMAS experiments: [Hg(DMSO)6](O3SCF3)2, δ = −2313 ppm and NEt4Na[Hg(CN)4], δ = −434 ppm. Using these new set-up samples, the set-up of 199Hg CPMAS experiments becomes fairly easy.

Only a handful of 199Hg chemical shift tensors have been reported in the literature. Several Hg–thiolate complexes, which can serve as models for [Hg(SCys)n] centers in the bacterial mercury resistance proteins, have been studied by solid-state 199Hg NMR. An enormous 199Hg CSA was observed for the linear Hg–thiolate complex, Hg(S-2,4,6-iPr3C6H2)2, Ω = 4479 ppm. A similarly large 199Hg chemical shift tensor was also reported for Hg2(NO3)2 · 2H2O, which contains an Hg–Hg bond, Ω = 3203 ppm.

Since Hg compounds often have large CSAs, it is desirable to perform CPMAS experiments with the highest spinning frequency possible in order to eliminate the spinning sidebands. However, as mentioned earlier, when the sample spinning frequency reaches about 10 kHz or higher, the CP efficiency often decreases drastically. An approach known as variable-amplitude cross-polarization (VACP) was demonstrated to be effective in circumventing this problem. In general, it is still difficult to obtain solid-state 199Hg NMR spectra.

4.2 Tin-119

Tin has three naturally occurring stable spin-1/2 isotopes: 115Sn (0.35%), 117Sn (7.61%) and 119Sn (8.58%). Among these, 119Sn exhibits the highest NMR sensitivity. The 119Sn chemical shift constant is 5% SnMe4 in CH2Cl2. The absolute 119Sn chemical shielding scale was recently established, which yields the absolute chemical shielding constant for SnMe4, σ = 2180 ± 200 ppm. This piece of information is necessary if one wishes to make direct comparisons between experimental 119Sn chemical shifts and ab initio shielding calculations. Typical 119Sn chemical shift values appear in a range of 800 ppm. The set-up sample for 119Sn CPMAS experiments is tetracyclohexyltin, (C6H11)4Sn, which is also used as a secondary reference sample, δ = −97.35 ppm.

The first 119Sn CPMAS NMR study was reported in 1978. Since then, solid-state 119Sn NMR has been applied to a large number of systems, including both inorganic materials and organotin compounds. A useful summary of solid-state 119Sn NMR applications in organotin chemistry was given by Sebold. Typical 119Sn CSAs are below 1000 ppm. The largest 119Sn CSA for diamagnetic tin-containing compounds is that for bis[trimethylsilyl]methyltin (Figure 9a), Ω = 1500 ppm. This compound also exhibits the most deshielded isotropic 119Sn chemical shift, δiso = 700 ppm (see Figure 9b).

Potentially, solid-state 119Sn NMR can be extended to the study of biological systems. For example, solution 119Sn NMR has been proved useful in the studies of protoporphyrin–hemoprotein interactions and of
new tin derivatives of antibiotics. Solid-state $^{119}\text{Sn}$ NMR is expected to be useful in these areas.

### 4.3 Platinum-195 and Lead-207

The stable spin-$\frac{1}{2}$ nuclei of platinum and lead are $^{195}\text{Pt}$ (33.8%) and $^{207}\text{Pb}$ (22.6%). These two nuclei have very similar $\gamma$ values so their NMR frequencies are also close, e.g., $\nu^{(195}\text{Pt}) = 107.100$ MHz and $\nu^{(207}\text{Pb}) = 104.630$ MHz at 11.75 T. The $^{195}\text{Pt}$ chemical shift standard is aqueous K$_2$PtCl$_6$. For $^{207}\text{Pb}$ NMR, the standard sample is 85% Me$_4$Pb in toluene. An external secondary reference sample of 1.0 M aqueous Pb(NO$_3$)$_2$ is often used in practice for $^{207}\text{Pb}$ chemical shift referencing, $\delta = -2961.2$ ppm.

The chemical shift range for both $^{195}\text{Pt}$ and $^{207}\text{Pb}$ is very large, approximately 16000 ppm. Such a large chemical shift range also suggests that the $^{195}\text{Pt}$ and $^{207}\text{Pb}$ CSAs must be large. In fact, a common feature of the solid-state $^{195}\text{Pt}$ and $^{207}\text{Pb}$ NMR spectra is the presence of a large number of spinning sidebands. The largest $^{195}\text{Pt}$ CSA was that found in K$_2$PtCl$_4$, $\Omega = 10.5 \times 10^7$ ppm, based on single-crystal $^{195}\text{Pt}$ NMR studies. In this case, MAS would not be very useful in eliminating the $^{195}\text{Pt}$ CSA.

For $^{195}\text{Pt}$ CPMAS experiments, the originally recommended set-up sample was K$_2$Pt(OH)$_6$.$^{129}$ However, it often takes at least 100 scans to see a reliable signal, making this sample not completely satisfactory. A better set-up sample, (NH$_4$)$_2$PtCl$_6$, was suggested by Hayashi and Hayamizu.$^{124}$ Using this sample, a $^{195}\text{Pt}$ CPMAS NMR signal can be observed after one pulse, $\delta = 240$ ppm at 300 K. The set-up sample for $^{207}\text{Pb}$ CPMAS experiments is (p-tolyl)$_4$Pb, $\delta = -148.8$ ppm.$^{125,126}$

It is well known that $^{195}\text{Pt}$ and $^{207}\text{Pb}$ NMR chemical shifts depend critically on the sample temperature at which the measurement is carried out. A recent study indicates that the solid-state $^{207}\text{Pb}$ NMR spectra of Pb(NO$_3$)$_2$ are highly sensitive to the variations of the sample temperature.$^{127}$ This study also reveals a localized heating effect caused by rapid sample spinning. The temperature-dependent phenomenon of solid Pb(NO$_3$)$_2$ suggests that this compound could be used for temperature calibration inside NMR probes.$^{128}$ Dybowski et al. have also studied the $^{207}\text{Pb}$ chemical shift tensors in a variety of lead salts and the novel Pb–Pb chemical bonding in lead oxides.$^{129-131}$

A potentially important but unexplored research area is solid-state $^{195}\text{Pt}$ and $^{207}\text{Pb}$ NMR of biological systems. Solution $^{195}\text{Pt}$ NMR has been shown useful in studying interactions between antitumor drugs and DNA molecules.$^{132}$ Similarly, solution $^{207}\text{Pb}$ NMR has been demonstrated as a new probe to calcium-binding proteins.$^{133}$ It might be possible to apply solid-state $^{207}\text{Pb}$ NMR to this type of metalloproteins, in analogy with the successful applications of solid-state $^{113}\text{Cd}$ NMR. Since $^{207}\text{Pb}$ exhibits a chemical shift range approximately 20 times that of $^{113}\text{Cd}$ (or three times of that of $^{199}\text{Hg}$), $^{207}\text{Pb}$ NMR should be more sensitive to the chemical environment at the metal active sites. Of course, the large $^{207}\text{Pb}$ CSAs may also make solid-state NMR measurement difficult.

### 4.4 Low-$\gamma$ Nuclei: Iron-57, Yttrium-89, Silver-109 and Tungsten-183

In addition to the common main group elements and the aforementioned metal nuclei, there is another class of spin-$\frac{1}{2}$ metal nuclei that are distinct from an NMR viewpoint. These metal nuclei, including $^{57}\text{Fe}$ (2.19%), $^{89}\text{Y}$ (100%), $^{103}\text{Rh}$ (100%), $^{107/109}\text{Ag}$ (51.82 and 48.18%), $^{183}\text{W}$ (14.40%) and $^{187}\text{Os}$ (1.64%), have very low $\gamma$ values and are sometimes known as the “Cinderella nuclei.”$^{134}$ Although in recent years these low-$\gamma$ nuclei have become increasingly accessible by solution NMR spectroscopy,$^{135}$ solid-state NMR studies for this class of nuclei are still rare. The major problems with solid-state NMR experiments for low-$\gamma$ nuclei include (a) exceedingly long spin–lattice relaxation times,
(b) large CSAs, (c) low intrinsic sensitivity associated with the low NMR frequencies and (d) acoustic ring effects of the NMR probe.

Despite all these difficulties, direct observations of $^{57}$Fe, $^{89}$Y and $^{183}$W NMR signals in solids have been demonstrated by Oldfield et al.\textsuperscript{(136–138)} and Dupree and Smith.\textsuperscript{(139)} In the solid-state $^{57}$Fe NMR studies, isotopic enrichment to 94.5% was employed to enhance the NMR signals. A large $^{183}$W CSA was reported for the “Keggin” compound, $\text{H}_3\text{[P(W_{12}O_{40})]}_n\text{H}_2\text{O}$: $\delta_{11} = 409$, $\delta_{22} = 148$ and $\delta_{33} = -1079$ ppm.\textsuperscript{(137)} Solid-state $^{89}$Y NMR has also been used to study high-$T_c$ superconductors YBa$_2$Cu$_3$O$_6$\textsubscript{+$\delta$}.\textsuperscript{(140)} For $^{107/109}$Ag, no direct observation of solid-state $^{109}$Ag NMR was made in any silver compound.

One seemingly obvious solution to some of the difficulties encountered in direct NMR observation of low-$\gamma$ nuclei is to transfer spin polarization from the abundant spins, namely the CP approach. However, the utility of CP under the Hartmann–Han$\text{h}$ condition to low-$\gamma$ dilute spins is faced with some practical problems. Merwin and Sebald have demonstrated CPMAS experiments for $^{89}$Y, $^{109}$Ag and $^{183}$W nuclei.\textsuperscript{(141–143)} They found that it is difficult to directly optimize the CP efficiency. Therefore, they used an alternative approach in practice. The recommended procedure is (1) to set the proton transmitter power to a relatively low level (90° pulse width = 10 $\mu$s), then (2) to use an oscilloscope to calibrate the power level at the observation channel according to the Hartmann–Han$\text{h}$ condition and finally (3) to use a solid sample to fine-tune the Hartmann–Han$\text{h}$ match.

A common feature of the CPMAS experiments involving low-$\gamma$ nuclei is that relatively long mixing times are required to achieve an appreciable degree of magnetization transfer. This is due to the fact that the dipolar interaction between $^1$H and low-$\gamma$ nuclei is always fairly weak as a result of the low $\gamma$ values of the metal nuclei and the long metal–proton separations. Under such circumstances, CPMAS works only for those systems with long $^1$H spin–lattice relaxation times in the rotating frame ($T_{1p}$). For systems with short $^1$H $T_{1p}$ values, the $^1$H magnetization would decay to zero even before any substantial transfer occurs. Therefore, the drawback of the CPMAS experiments for low-$\gamma$ nuclei is that it is difficult to predict whether or not one could observe any CP signals. For this reason, it is highly recommended that one measures $^1$H $T_{1p}$ for the system in question before attempting CPMAS experiments. Another potentially important problem is that the CP efficiency decreases with spinning speed. As mentioned earlier, new CP techniques such as RAMP-CP or VACP should also be useful to low-$\gamma$ spin-1/2 nuclei. Perhaps the only advantage associated with low-$\gamma$ metal nuclei is that since the dipolar interactions between protons and low-$\gamma$ metal nuclei are weak, it is often not so critical to have very high RF power for $^1$H decoupling.

5 SECOND-ORDER QUADRUPOULAR EFFECTS ON SPIN-1/2 SPECTRA

In the above discussion, we have assumed that MAS can completely average the heteronuclear dipolar interaction between two dilute spins. This assumption is, however, only valid for cases where the two interacting spins are both spin-1/2 nuclei. If the spin-1/2 nucleus under study is dipolar coupled to a quadrupolar nucleus (spin number $> 1/2$), the dipolar interaction between the two spins cannot be completely removed by MAS. This arises from the fact that the quadrupolar spins are no longer quantized along the direction of the external magnetic field due to the presence of the quadrupolar interaction. Consequently, the so-called “residual dipolar couplings” are often observed in the MAS spectra of spin-1/2 nuclei. The quadrupole perturbation on magnetic dipolar interactions was first noticed in solid-state $^{19}$F and $^1$H NMR spectra of stationary samples,\textsuperscript{(144,145)} and later observed in $^{13}$C MAS NMR spectra.\textsuperscript{(146,147)} However, most of the recent cases are concerned with MAS spectra of spin-1/2 nuclei other than $^{13}$C and $^1$H. Therefore, it is worth discussing this subject further. In the discussion that follows, we present an example from the recent literature to illustrate the effect. More complete coverage of the literature can be found in the review article by Harris and Olivieri.\textsuperscript{(148)}

Figure 10(a–d) shows the isotropic region of the $^{31}$P MAS spectra of all-\textit{trans}-Ru(PEt$_3$)$_2$(CO)$_2$(C=CPh)$_2$.\textsuperscript{(149)} The spectrum exhibits an intense central peak and small satellite peaks. The intense peak is due to the $^{31}$P nucleus. The spectrum exhibits an intense central peak and small satellite peaks. The intense peak is due to the $^{31}$P nucleus. Since both $^{99}$Ru (12.7%) and $^{101}$Ru (17.1%) are spin-1/2, one might expect the $^{31}$P CP MAS spectrum of a molecule containing an Ru–P spin pair to consist of six equally spaced peaks, arising from the six different spin states, $m_Z = \pm 3/2, \pm 1/2, \pm 1, \pm 3/2$ and $\pm 5/2$. However, as clearly seen from Figure 10(a–d), the separations between the satellite peaks are “squeezed” at the high-frequency end and “stretched” at the opposite direction. These uneven separations between the satellite peaks are due to the different degrees of mixing between $^1/J$(Ru,P) and the “residual dipolar coupling”. Analysis of this type of NMR spectra can yield information about $^1/J$(99/101Ru,$^{31}$P), 99/101Ru quadrupole couplings and 99/101Ru–$^{31}$P dipolar couplings. Since direct NMR observation of quadrupolar nuclei is often difficult, the second-order quadrupole effect on spin-1/2 spectra is an
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 10 (a) Isotropic region of the $^{31}$P CPMAS spectrum of all-trans-Ru(PEt$_3$)$_2$(CO)$_2$(C≡CPh)$_2$ obtained at 81.0 MHz. (b) Expansion of the satellite peaks in (a). effective way of studying quadrupolar nuclei indirectly. Since the “residual dipolar couplings” are proportional to the quadrupolar coupling constant at the quadrupolar nucleus and inversely proportional to the external magnetic field strength, this phenomenon is important in cases where either large quadrupolar interactions are present or the NMR experiments are performed at low magnetic fields.

6 CONCLUDING REMARKS

In this article, we have described some basic principles and applications of solid-state NMR for spin-$\frac{1}{2}$ nuclei other than $^1$H and $^{13}$C. Emphasis has been placed on the fundamental and practical aspects of solid-state NMR for a group of selected spin-$\frac{1}{2}$ nuclei. The field of solid-state multinuclear NMR spectroscopy is not only diverse, but also rapidly expanding. It is therefore not possible within the limited space to provide a complete account. It is hoped that this article can provide readers with a brief overview of this branch of scientific research and a starting point to the extensive solid-state NMR literature.

Solid-state Nuclear Magnetic Resonance

Rex E. Gerald II
Argonne National Laboratory, Argonne, USA

The first experimental verification of nuclear magnetic resonance (NMR) in the solid state by Edward M. Purcell, Henry C. Torrey, and Robert V. Pound occurred on Saturday afternoon, December 15, 1945. Since then, new developments have transformed this form of spectroscopy from an interesting physical curiosity at its inception to one of the most widely used analytical tools for physical, chemical, biological, and materials research and applications. The capabilities of NMR include identification of molecules in all phases of matter by their atomic connectivities; probing the temperature-dependent conformation of molecules from cyclohexane to complex 50 kilo-Dalton proteins; molecular dynamics investigations from the picosecond timescale for rotation of small molecules to the second timescale for atoms diffusing throughout the three-dimensional nanoscopic channels of zeolites; elucidation of chemical reaction mechanisms; the determination of organization, reorientation, and diffusion of molecular solids; the identification of phase changes and morphology of solids; the measurement of bond lengths and interatomic distances between nonbonded atoms; the assessment of pore size in nanoporous solids as well as identification of adsorbates and their diffusivities; the estimation of physicochemical parameters of molecular systems such as equilibrium and kinetic rate constants, enthalpies and entropies of a reaction, and activation energies; the capability to follow a metabolic pathway taking place inside living cells; the quantification of the alignment of molecules in partially ordered systems; the determination of nanoscale domain sizes in heterogeneous materials; and the noninvasive imaging of all phases and forms of matter under various temperature, pressure, and mechanical conditions.

The scope of this article is very selective, covering some of the most widely used techniques and more unusual areas of application of solid-state NMR. These topics are covered at different levels of detail, and some are just mentioned by reference to published work. This article is not intended to present a comprehensive review of all state-of-the-art NMR techniques; for these the reader should consult references included in the text. Instead, this article provides a historical background and the fundamental concepts of magnetic resonance that preceded solid-state NMR, a general overview of the basic principles with emphasis on the visualization of anisotropic spin interactions, a review of the most widely used methods for investigating solids by NMR, and practical information to provide a modicum of guidance for application of the methods. There are several redundancies in terminology so that different sections can be read independently.

The references are an important component of the article and should be consulted for more complete and often original accounts of the theory and techniques for the application of NMR to solids. A modest attempt was made to include original and important references, but more
important, many were included to provide examples of chemical and physical insights arrived at in whole or in part by application of NMR techniques to the investigation of the problem. For figures and tables, if no reference or acknowledgment is provided, the spectrum or photograph in the figure or the table was previously unpublished.

The article is directed at a general audience of chemical and physical analytical scientists with an interest in NMR. In addition, NMR spectroscopists may find some interesting details of studies on metals and magnetic materials.

1 INTRODUCTION

In its present form, NMR spectroscopy is the application of highly evolved methods for manipulating nuclear spins, the purpose of which is to elicit a quantitative understanding of an atom’s local environment and dynamics. NMR is rooted in quantum mechanics. A 1936 report by C.J. Gorter on the attempt to observe the NMR effect was founded on the quantum mechanical concept of energy transitions in two-level systems. Gorter’s experimental approach to record the first NMR response was based on a thermodynamic measurement. He understood the underlying theory and his estimation of the magnitude of the NMR effect was reasonable. Unfortunately, his attempt failed because the compounds he chose to investigate do not have an efficient pathway to dissipate energy from the system of spins to a calorimeter for measurement. Without an efficient energy pathway, any nuclear spin system will saturate when it is subjected to resonant energy. Without the absorption or emission of energy, the NMR effect cannot be detected.

At the time Gorter was performing these experiments, Isador I. Rabi was developing an interest in the spatial separation of atoms in atomic beams by the attractive and repulsive action of an inhomogeneous magnetic field on atomic magnetic moments that were both electronic and nuclear in origin. After setting up a laboratory of his own, Rabi demonstrated a mechanical method for flipping nuclear spins. The approach was rooted in the spatial quantization of spin angular momentum; however, Rabi used his keen kinematic sense for the behavior of classical angular momentum to develop the idea. He used his insight to envision the first (mechanical) manipulation of the orientation of a nuclear spin. Meanwhile, Gorter continued to report unsuccessful attempts to measure NMR transitions in compounds in the solid state. Following a short visit by Gorter to Rabi’s laboratory, the Rabi group demonstrated the first successful NMR effect in a molecular beam experiment. Gorter was an influential factor. Several years later, a student of Rabi’s, along with two collaborators, reported the detection of the NMR phenomenon in a solid compound by means of a radiofrequency apparatus. The following sections describe in greater detail the events that lead to the discovery of NMR in condensed matter.

1.1 Spatial Dispersion of Atomic Magnetic Moments in Magnetic Fields

The study of gas phase atomic magnetic moments in inhomogeneous magnetic fields provided the fundamental concepts for the manipulation of nuclear spins. Experiments that probed atomic and nuclear magnetic moments in molecular beams formed the basis for the first successful NMR experiments. These experiments were conducted in the laboratory of I.I. Rabi at Columbia University in the 1930s. The events that initiated Rabi’s interest in molecular beams began earlier, in 1927, when he was awarded a Barnard Fellowship (September 22, 1927–June 8, 1928). Upon hearing of his award, Rabi applied for a leave of absence from his teaching duties in physics at the College of the City of New York. His request was denied. Shortly thereafter, he submitted a letter of resignation to the College and left for Europe to advance his understanding of the emerging radical new theories in physics, collectively called the new quantum mechanics. It had been eight years since he graduated with a PhD degree in chemistry from Cornell University, and he had grown restless in his teaching position. Unannounced, Rabi visited Erwin Schrödinger in Zurich, Arnold Sommerfeld in Munich, and Niels Bohr in Copenhagen. Bohr arranged for Rabi and a fellow student to go to Hamburg and work with Wolfgang Pauli.

Otto Stern, also in Hamburg at that time, was preparing a series of papers detailing studies on isolated atoms using his molecular beam method. In December 1927, Rabi suggested to Stern that an atomic beam could be directed into a well-defined homogeneous magnetic field at an oblique angle to separate atomic spin states. This technique could replace the traditional Stern–Gerlach method that relied on atomic deflection in an ill-defined inhomogeneous magnetic field. According to Rabi’s idea, the spins would be separated spatially according to their orientation (spin-up or spin-down), just as white light separates into its components as it passes through a homogeneous glass prism. Stern thought Rabi had an unusual but reasonable idea, since an accurate calibration of an inhomogeneous field was difficult to achieve, and this shortcoming limited the accuracy of the determination of the fundamental magnetic properties of atoms. The keys to the Rabi method are the homogeneous field and the oblique angle trajectory. The advantage of the inhomogeneous magnetic field, used by Stern, is that the force is larger on one pole of a magnetic moment, and the spin moves in the direction of the magnetic field.
gradient, or in the opposite direction, according to its orientation. A homogeneous field is easier to calibrate, but if the beam of spins were directed in the usual way, head-on, into a homogeneous field, then no splitting of the beam would occur because the magnetic force on the north and south pole of each magnetic moment would be equal and opposite. Rabi overcame this problem by aiming the beam into the field at an oblique angle, which refracted the beam. At Stern’s invitation, Rabi set out to demonstrate his idea experimentally by using a beam of potassium atoms, and this later proved to be successful. Rabi’s method for deflecting molecular beams was the first use of the homogeneous magnetic field (the Rabi field) that he later used for his famous resonance experiments.

1.2 Nuclear Spin Flips in Molecular Beams

The experiments that separated atoms in space by attracting and repelling their electronic magnet moments led Otto Stern and his coworkers to consider how they might flip the spins in a beamlet that contained atomic spins of only one orientation; Rabi also wondered how he might flip the much weaker nuclear spins in a beamlet of polarized nuclear spins. While in Europe, Rabi was elated to receive an offer from Columbia University, his alma mater, for a lectureship in the physics department. He promptly accepted and within two years had set up his own molecular beam laboratory. For a period of about five years Rabi and his students made many measurements in his “Rabi field” to determine the magnetic properties of nuclei. He used the refocusing and zero-moment methods that he and his students developed.\(^2\)\(^–\)\(^1\)\(^1\)

The transition field or T-field method, also conceived by Rabi, provided the avenue for measuring the sign and hence the sense of precession of a nuclear magnetic moment in an external magnetic field.\(^3\)\(^–\)\(^1\)\(^2\)\(^–\)\(^1\)\(^7\) Two parallel wires carrying equal direct currents in the same direction created the transition field. A point of uniform magnetic field resulted between the two wires. On either side, away from both wires, the field was equal in intensity, but exactly opposite in direction, as illustrated in Figure 1. A nuclear magnetic moment of selected orientation was directed between the parallel wires and subjected to an abrupt change in the direction of the magnetic field. A transition or reorientation of the spin would take place in the process. The success of the T-field method was the impetus for the subsequent development of the resonance method; it was the drive to determine the sign of the nuclear magnetic moment that led Rabi to propose and use the T-field to manipulate the spatial orientation of a spin.

Prior to Rabi’s early molecular beam work at Columbia University, Otto Stern in Hamburg had set out to test the idea of space quantization. Stern attempted to change the orientation of an atomic spin (of a potassium atom) prepared in an inhomogeneous magnetic field by passing it into a second, similar magnetic field, but one oriented in the opposite direction. Stern determined that on slow passage through two sequential magnetic fields of opposing senses (a transition field), the atomic spin maintained the same orientation. However, if the atomic spin was passed through the field inversion rapidly, then the spin did invert its orientation. Rabi later expounded on this effect in his 1936 paper titled “On the Process of Space Quantization”\(^1\)\(^2\). A particle traveling through such a T-field would be subjected to a spatially abrupt change in the field direction from one sense to the opposite sense. This abrupt field inversion (or spatial gyration of the field as viewed by the moving particle) would couple to the precessing magnetic moment as it moved through the field. Rapidly moving a particle through the field inversion was equivalent to affecting a spin flip by applying a rotating field to a particle fixed in space. From the perspective of the particle, the effect was the same: the orientation of the nuclear spin was changed. This is the essence of NMR as it is applied today – the reorientation of spins in a controlled manner – but it was originally accomplished in a mechanical fashion and without the use of radiofrequency fields.

In the T-field method, the velocity of the particle and the spatial dimension over which the magnetic field inverted direction were used to calculate the rate of gyration that, in effect, the field would have from the perspective of a precessing magnetic moment in the nominal homogeneous magnetic field. If the frequency of precession of a nuclear magnetic moment was close to the apparent frequency of motion of the gyrating magnetic field, then there would be a strong coupling between the two and the gyrating field would change the orientation.
of the nuclear spin. Rabi explained this in his 1937 paper titled “Space Quantization in a Gyrating Magnetic Field” in terms of a probability for flipping the spin.\(^{18}\) A close match between the precession (or Larmor) frequency and the frequency of the gyrating magnetic field resulted in a high probability for nuclear spin reorientation, while a mismatch between the frequencies resulted in a concomitantly lower transition probability. The type of mechanical spin flip performed by Rabi’s group, in retrospect, represented the first application of a \(\pi\) (180°) pulse to a nuclear magnetic moment, and it was accomplished without the application of a radiofrequency pulse, as would commonly be done today. The term “resonance”, adopted later, was a suitable term to describe this interaction because the procedure for reorienting a magnetic moment required that the gyrating magnetic field move in a fashion coincident or resonant with the precessing magnetic moment. The physical intuitions, concepts, and theoretical underpinnings of manipulating the orientation of nuclear spins in magnetic fields were established. The stage was set for the experimental observation of NMR in the condensed phase.

### 1.3 Early Attempts at Recording Nuclear Magnetic Resonance in Condensed Matter

The first published attempt to measure an NMR response in condensed matter was reported by C.J. Gorter in 1936.\(^{11}\) This unsuccessful experimental attempt was made on the \(^7\)Li isotope of lithium in solid lithium fluoride (LiF) and on the \(^1\)H isotope of hydrogen in the solid double salt potassium alum (KAl(SO\(_4\))\(_2\)-12H\(_2\)O). The experiments were performed at 20 K to take advantage of the larger Boltzmann magnetization available at low temperatures.\(^{19}\) Gorter viewed the nuclear spin from the perspective of quantum mechanics. Thus, a nucleus with spin 1/2 will have two different orientations in a static magnetic field. The separation between the two energy levels is proportional to the strength of the magnetic field, and transitions from one energy level to the other occur in the presence of a transverse oscillating magnetic field. The apparatus that Gorter used to search for the NMR effect consisted of a variable field magnet (0–1.2 T) of poor homogeneity (~1% over the sample volume) by modern NMR standards, an oscillator that produced a 20-MHz radiofrequency magnetic field of several gauss, and a calorimeter.

Gorter’s idea was to induce nuclear spin transitions with the radiofrequency field; following excitation, the spins would then relax back to a thermal distribution of orientations, and the energy given off by the spins to the surroundings (the lattice) would cause the temperature of the calorimeter to rise. The spins, in effect, would act as a conduit for transferring radiofrequency energy from the oscillator to the calorimeter. (A direct transfer of energy from the oscillator to the calorimeter occurred at a constant rate, and was taken into account.)

Gorter surmised that his experimental attempt to measure the NMR effect failed because the rate of energy transfer from the nuclear spins (in the excited state) to the lattice was too slow. That is, the spin-lattice relaxation rate was so small that the spin system saturated, and sufficient energy could not be transferred from the oscillator to the calorimeter, via the nuclear spins, in a short enough time to record a temperature change above the background level. Gorter also pointed out later that the experimental failure could be accounted for by viewing the results as a nuclear response with an inhomogeneous linewidth on the order of 10\(^6\) Hz.\(^{19}\) Presumably, the broad distribution of resonances and the slow modulation of the magnetic field (that was used to bring the nuclear spins into resonance) were not optimized for a measurable rate of energy transfer from the oscillator, via the nuclear spins, to the calorimeter. Thus, prior to Rabi’s conceptual and later actual manipulation of spins, described by classic torque action, radiofrequency magnetic fields were applied to nuclear spins to affect incoherent transitions.

In September 1937, Gorter visited the physics department at Columbia University. Rabi was aware of his work in condensed matter physics, and after they discussed Rabi’s mechanical concepts of the coupling of a gyrating magnetic field with a precessing nuclear magnetic moment, Gorter asked why Rabi’s group was not using a radiofrequency magnetic field to reorient the nuclear spins. Rabi began to sense that he had a competitor. Hence, in addition to the continuing productive activity by Rabi’s group with the refocusing effective zero-moment, and T-field methods for studying nuclear magnetic moments, Gorter’s visit provided the stimulus for Rabi to develop the experimental apparatus required to attempt the resonance method.

### 1.4 First Successful Report of Nuclear Magnetic Resonance Phenomenon

Isador Rabi, Polykarp Kusch, Jerrold Zacharias, Jerome Kellogg, and Sidney Millman modified a molecular beam apparatus to accommodate a homogeneous magnetic field and radiofrequency coil for an attempt at observing the resonance effect in a molecular beam. They used a beam of lithium chloride (LiCl) molecules, and the resonance condition was set for \(^7\)Li nuclei in a magnetic field of 0.21 T. In January 1938, they conducted the first successful experiment that demonstrated the resonance of a nuclear magnetic moment with a radiofrequency magnetic field. Their apparatus for this experiment consisted of three in-line magnets contained in a high-vacuum chamber. While
traversing the first inhomogeneous field, the beam of LiCl molecules was separated into four beamlets: two spin-up and two spin-down. (A \(^7\)Li nucleus has a spin angular momentum quantum number, \(I\), of \(3/2\).) The theory of quantum mechanics states that a particle with \(I = 3/2\) can only have \(2I + 1 = 4\) discrete orientations in space (space quantization). The discrete orientations are with respect to the axis of quantization, which is determined by the direction of a force field (in this case, the magnetic field). The orientation of a \(^7\)Li nucleus in a magnetic field is given by its magnetic quantum number. Each beamlet contained LiCl molecules with the same magnetic quantum number for the \(^7\)Li nucleus: +3/2 (spin-up), +1/2 (spin-up), −1/2 (spin-down), −3/2 (spin-down). The beamlets then passed through a hairpin-type radiofrequency coil that was located in the center of a second, homogeneous field. As long as the coil was not energized, the nuclear magnetic moments maintained their orientation on passing through this homogeneous field. The beamlets then passed through the third field, which was inhomogeneous, like the first, but oriented in the opposite direction, so that the beam would be refocused onto a detector. Provided the radiofrequency coil was not energized, the molecular beam diverged in the first field, traversed the second field unchanged, converged in the third field, and arrived at the detector intact. Under these conditions, the detector recorded a maximum beam signal. The radiofrequency coil was then energized at a constant frequency of 3.518 MHz, and the strength of the static, homogeneous magnetic field surrounding the coil was adjusted so that the frequency of precession of the nuclear magnetic moment of the \(^7\)Li nuclei in the LiCl molecules would match the frequency of the oscillating magnetic field. This was considered to be the condition for mutual resonance between the precession of the nuclear magnetic moment and the rotation or gyration of the radiofrequency magnetic field. The condition of resonance caused a torque to act on the nuclear spin angular momentum, resulting in a reorientation or flip of the nuclear magnetic moment. Upon passing through the first (inhomogeneous) magnetic field, the spin-up nuclear magnetic moments were diverted to one side, while the spin-down moments were diverted to the opposite side. The third magnetic field, which was also inhomogeneous, turned each beam back towards the center. However, when each beamlet traveled through the homogeneous field with the radiofrequency magnetic field in operation at the resonance frequency of the \(^7\)Li spins, spin-up nuclear magnetic moments traveling to the left suddenly flipped and became spin-down moments on the same course. On entering the refocusing (inverted) inhomogeneous magnetic field, this beam was further deflected to the left and not refocused. The analogous process occurred for the spin-down nuclear magnetic moments, and they too diverged and were not refocused. The detector, under the resonance condition, showed a dramatic reduction in beam signal output, as shown in Figure 2.

This success represented the first manipulation of nuclear spins in a homogeneous magnetic field by a rotating magnetic field that was generated by a radiofrequency oscillator.\(^{20}\) It demonstrated (from the perspective of the nucleus) the fundamental concept of applying a torque to reorient a nuclear magnetic moment using a radiofrequency magnetic field. This accomplishment stands as a very significant step toward NMR experiments on condensed matter. The elements of a static homogeneous magnetic field and a radiofrequency magnetic field provided the avenue to leave the arena of rarefied matter and the spatial selection of unity polarization and enter the arena of condensed matter where nuclear polarization was determined by a Boltzmann distribution of spin orientations. Rabi’s research efforts would continue in the gas phase, but the stage was set for NMR of solids.

A second published report by Gorter and Broer in 1942 indicated a subsequent unsuccessful attempt to record \(^7\)Li NMR of lithium chloride (LiCl) and \(^{19}\)F NMR of potassium fluoride (KF). The failed attempts were attributed to insufficient development of an initial Boltzmann nuclear polarization in a reasonable time or to a saturation of the nuclear magnetization during the experiment. That is, the nuclear spin-lattice relaxation rates for the pure substances at low temperature may have been exceedingly small.\(^{19,21,22}\) Relaxation of nuclear magnetic moments in external magnetic fields was a key question at the time when the first NMR experiments in the condensed matter were attempted. Gorter discovered paramagnetic relaxation and was keenly aware of the

Figure 2 The decrease in beam intensity metered by the detector demonstrated the resonance condition for the \(^7\)Li nuclei in a beam composed of isolated LiCl molecules. [Adapted from I.I. Rabi, I.R. Zacharias, S. Millman, P. Kusch,\(^{53}\); A New Method of Measuring Nuclear Magnetic Moment’, Phys. Rev., 53, 318 (1938).]
potential problems that small relaxation rates for nuclear magnetic moments could cause for the observation of the NMR phenomenon. In consideration of his broad understanding of low-temperature physics and of paramagnetism in particular, and his many attempts to detect the NMR effect, Gorter argued that simple bad luck played a role in his misfortunes in the initial observation of NMR in condensed matter. The preponderance of evidence indicates that Gorter was searching for NMR phenomena in condensed matter for about 14 years prior to the first successful reports. It is unfortunate that his contributions to NMR are not widely recognized. A photograph of Professor Gorter is shown in Figure 3.

1.5 Original Nuclear Magnetic Resonance Experiments in the Solid State

The first successful NMR experiments in a solid material, namely paraffin wax (a mixture of solid alkanes, $C_{23}-C_{29}$, with a melting point in the range 50–60 °C), was reported by Edward Purcell, Henry Torrey, and Robert Pound just after the end of World War II in 1945. Independently, F. Bloch, W. Hansen, and M. Packard reported the first successful NMR experiments in a liquid, namely water. Both groups recorded NMRs for the $^1H$ isotope of hydrogen. It is interesting to note that the suggestion by Edward Purcell that the resonant absorption of radiofrequency energy might be detected by nuclear magnetic moments when placed in an external magnetic field came about because of the confluence of scientists at the Massachusetts Institute of Technology Radiation Laboratory for war-related research on radar, the tedious task of documenting the radar work, and the lack of access to previously published reports of unsuccessful attempts by C.J. Gorter in German-occupied Holland.

Prior to working at the Radiation Laboratory, Henry Torrey was a graduate student of I.I. Rabi. He measured the sign of the nuclear magnetic moment of $^{23}$Na and $^{39}$K using the transition field method. Rabi had won the Nobel Prize one year earlier (physics, 1944) for his molecular beam resonance method that was used to study nuclear magnetic moments. He and his students were renowned in Europe and the United States. Therefore, Torrey was an appropriate person for Purcell to approach with such an idea.

The experiment was conducted at nearby Harvard University because the magnet that would produce the first observed NMR in condensed matter was located there, and its owner, J. Curry Street, offered use of it to the trio. Robert Pound recounted that the detection of resonance absorption by nuclear spins was initially missed because the iron core of the magnet saturated unexpectedly and a magnetic field calibration error resulted. The detector that was used was not a Helmholtz or solenoid coil, although these types of coil are almost exclusively used in modern NMR probes for small solid and liquid samples. Instead, having spent the previous five years on microwave technology, Purcell and co-workers constructed a modified microwave cavity resonator that was designed to operate at the macrowavelength of 10 m. Operation at this radiofrequency wavelength was dictated by the predicted resonance frequency for
the nuclei of protons in paraffin wax when immersed in a magnetic field of 7 kG, such that the resonance absorption would be at a frequency of approximately 30 MHz. Their capacitively shortened, mica-dielectric coaxial cavity resonator is shown in Figure 4. It is similar to the so-called toroid cavity detector used by the author.\textsuperscript{30,31}

Coaxial or toroid cavity NMR detector devices are quite simple in construction and consist of a metal can, usually made of copper, with a central conductor of copper wire. The cavity was used as a device to contain the sample and couple the resonant energy to the nuclear spins. Coupling energy into and out of the resonator is achieved by several methods. A set of two magnetic coupling loops (one for input, the other for output) can be inserted in the wall of the cavity, as Purcell and co-workers did. Another approach couples the radiofrequency energy into the cavity via a loading capacitor located at one end of the resonator; detection of the nuclear induction proceeds through the same port. The NMR effect in a two-pound sample of paraffin wax was demonstrated by the observation of a decrease in the output of a magnetic coupling loop, located opposite the loop used to energize the cavity, when at the specified magnetic field strength the proton nuclear spins absorbed energy. Thus, the energy detected in the cavity was attenuated because it was absorbed by the nuclear spins.

The proton NMR experiments conducted on paraffin wax demonstrated that the nuclear spins absorbed radiofrequency energy that was present in the cavity. The condition necessary for energy absorption by the sample was that the magnetic field intensity split the energy levels occupied by the nuclear magnetic moments of the hydrogen nuclei to an energy separation equal in value to the energy that was resonant in the cavity. However, this NMR experiment could be performed in a different manner. Instead of detecting the absorption of energy, the resonant emission of energy could be detected from the nuclear spins following an impulse of coherent excitation using radiofrequency energy. This approach, applied with a variety of different inductors, including Helmholtz and solenoid coils, single loops, Litz coils, and cavities, is the most common way that NMR experiments are performed today.

The resonator used by Purcell, Torrey, and Pound produced radiofrequency magnetic flux in concentric circles. This circular field geometry is very different from the unidirectional fields produced in the central volume of Helmholtz and solenoid coils. Coherent movement (flow) of nuclear spins in such a cavity produces NMR spectra with unusual properties, as shown recently by Gerald et al.\textsuperscript{32} It is not uncommon that revisiting old approaches with modern equipment can lead to interesting and novel ideas and applications.

2 BASIC PRINCIPLES AND THEORY

NMR spectroscopy provides direct energy measurements of the interactions between electromagnetic fields and nuclei with spin. All nuclei with spin have a magnetic dipole moment; those with spin quantum number greater than the minimum of 1/2 also have an electric quadrupole moment. The magnetic and electric fields can be applied externally or come from the electronic structure surrounding the nuclei; they can also be static or dynamic. It is usually the case that nuclei in molecules at room temperature are simultaneously subjected to a combination of external and internal magnetic and electric fields that are both static and dynamic. The study of NMR spectroscopy and nuclear spin relaxation is founded on the quantum mechanics of spin interactions. Semiclassical and phenomenological treatments of spin interactions are widely used and provide a practical starting point for understanding NMR in solids.\textsuperscript{33–36}

2.1 Nuclear Spins and Moments

Of the nuclei in the periodic table, most are said to be “NMR active”. In a semiclassical treatment, these nuclei are viewed as charged structures that have an “intrinsic” or “spin” angular momentum given by $\vec{I}$, where $\hbar$ is Plank’s constant and has units of angular momentum, and $\vec{I}$ is the dimensionless operator for angular momentum. The nuclear spin quantum number is a dimensionless, scalar quantity that is always positive and of magnitude $n/2$, where $n = 0, 1, 2, \ldots$; it is directly proportional to the maximum projection (z-component) of the total spin angular momentum onto the axis of spatial quantization. Several commonly investigated nuclei, including $^1$H, $^{13}$C, and $^{19}$F, have the smallest spin quantum number, 1/2. An isomer of the hafnium nuclides, $^{177m2}$Hf, has one of the largest nuclear spin quantum numbers, 37/2. The angular momentum of the nucleus is thought to be associated with the movement of constituent nuclear charge and has a sign, + or −. The orbiting charged particles that constitute the nucleus generate electric currents that, in turn, produce a nuclear magnetic moment, $\vec{\mu}$, given by $\vec{\mu} = \gamma \vec{I}$, where $\gamma$ is the nuclear magnetogyric ratio.

Tables exist that give $\gamma$ for NMR-active nuclei.\textsuperscript{37–39} The nuclear magnetic moment also produces a dipolar magnetic field. Thus, a nucleus that possesses angular momentum, designated by a polar vector, has a magnetic moment, also designated by a polar vector; the two polar vectors are parallel when $\gamma$ is positive and antiparallel when $\gamma$ is negative. The sum of the z-components of the nuclear magnetic moments in an ensemble of spins constitutes the nuclear spin magnetization of the sample. Nuclei in which the constituent charge is not spherically distributed in space also possess an electric
quadrupole moment (nuclear electric dipole moments are theoretically not allowed). This electric moment produces an associated electric field that is different from the field produced by a point charge. Also, the orientation of the electric quadrupole moment is rigidly tethered to the orientation of the magnetic dipole moment. An electric field gradient and a homogeneous magnetic field can simultaneously interact with the nucleus and compete to align the nuclear angular momentum in the respective field directions.

2.2 Actions of Nuclear Spins in Magnetic Fields

The spin of an atom or nucleus is equivalent to the spin of a toy top. The spin in both cases imparts an angular momentum. The angular momentum, like any momentum, resists change. Gravity, acting on a slightly tilted spinning top, imparts a downward force on the angular momentum. The result is a torque that causes the top to precess about the direction of the gravitational field. The spin angular momentum of a nucleus and the magnetic moment of that nucleus are rigidly tethered together. A magnetic field acting on the tilted magnetic moment (tilted due to spatial quantization), in analogy to the gravitational field acting on the toy top causes the nuclear spin to precess about the direction of the magnetic field. Thus, like the top, the nuclear spin simultaneously spins about its own axis and precesses about the magnetic field direction. The spin rate determines the magnitude of the angular momentum, while the sense or sign of spin rotation determines the direction of the angular momentum. In turn, the magnitude and sign of the angular momentum determine the rate and sense (or the sign) of precession. The intrinsic nature of the spin angular momentum means that the rate of rotation of the nuclear spin is constant. And, therefore, the precession frequency (called the Larmor frequency) is also constant. For a toy top, in contrast, frictional forces slow the rate of rotation and thus the rate of precession.

A nuclear spin, precessing in a static magnetic field, can be manipulated by the application of an additional magnetic field that rotates synchronously with the precessional motion. The concerted effect of the rotational magnetic field, \( \mathbf{B}_1 \), and the static magnetic field, \( \mathbf{B}^{\text{ext}} \), is analyzed in a frame of reference that rotates in step with the precessional motion of the nuclear spin, which is due only to \( \mathbf{B}^{\text{ext}} \). In such a rotating frame, \( \mathbf{B}^{\text{ext}} \) vanishes. If the frame of reference rotates at a rate different from the rate of precession of the spins then a pseudo (or offset) magnetic field \( \Delta \mathbf{B}^{\text{ext}} \) results. The magnitude of \( \Delta \mathbf{B}^{\text{ext}} \) would be commensurate with the difference between the different rates of rotation. Spin precession in synchronous and asynchronous rotating frames is illustrated in Figure 5.

An ensemble of identical spins will precess about \( \mathbf{B}^{\text{ext}} \) at the same rate; however, each will have an instantaneous random position. That is, their phases are not correlated. The sum of all projections of nuclear magnetic moments in thermal equilibrium on the axis defined by the static field direction is the Boltzmann nuclear magnetization, \( \mathbf{M} \). The rotating frame is useful for following the trajectory of the nuclear magnetization as it is manipulated by transient magnetic fields and then allowed to recover to equilibrium, subject only to \( \mathbf{B}^{\text{ext}} \) and internal fields. The action of \( \mathbf{B}_1 \) (in the synchronous or on-resonance rotating frame) on \( \mathbf{M} \) is illustrated for two transient pulses in Figure 6.

The application of a \( \pi/2 \) pulse rotates or nutates \( \mathbf{M} \) by 90°; similarly, a \( \pi \) pulse rotates \( \mathbf{M} \) by 180°, that is, \( \mathbf{M} \) is completely inverted. In each case, \( \mathbf{M} \) nutates only during the application of \( \mathbf{B}_1 \). The action of \( \mathbf{B}_1^{\text{ext}} \), the vector sum
of $B_1$ and $\Delta B^{\text{ext}}$ (in the asynchronous or off-resonance rotating frame) on $M$ is illustrated in Figure 7. It is usually the case that $B_1 \gg \Delta B^{\text{ext}}$, so that the magnetization nutates in a plane (very nearly) perpendicular to $B_1$. Following the application of $B_1$, $M$ is free to precess about $B^{\text{ext}}$ in the laboratory frame and induces a voltage in a nearby receiver coil. The signal, a free induction decay (FID), is transformed from the time domain to the frequency domain (NMR spectrum) by the fast Fourier transform (FFT) algorithm.

2.3 Isotropic Nuclear Spin Interactions

The coupling between a nuclear magnetic moment and an externally applied homogeneous magnetic field that defines the laboratory $z$-coordinate, $B^{\text{ext}} = (0, 0, B_0)$, is an isotropic interaction. The Zeeman Hamiltonian describes it: $H_z = -\mu \cdot B^{\text{ext}}$. Only the dot-product term between the angular momentum component $I_z$ and the nonzero magnetic field component survives, so that $H_z = -\gamma B_0 I_z$. The eigenvalues of the Zeeman Hamiltonian are the energies associated with the transitions between the energy levels that are occupied by the nuclear spin when it is placed in the magnetic field: $E_m = -\gamma I_0 B_0 m$. (The operation of $I_z$ on a state of a spin with intrinsic angular momentum quantum number $I$ results in an eigenvalue $m$, called the nuclear magnetic quantum number, that ranges from $-I$ to $+I$ in unit increments.) These energy levels are thought to correspond to discrete angular orientations of the spin angular momentum vector with respect to the direction of the external magnetic field (this correspondence is termed space quantization). Transitions are allowed between adjacent Zeeman energy levels ($\Delta m = 1$) such that the frequency of electromagnetic radiation needed to effect a transition is $\Delta E = \gamma I_0 B_0 = hw_0$, where $w_0$ is called the Larmor frequency. An NMR-active nucleus placed in a magnetic field experiences a force that arises from the interaction between the field and the component of the magnetic moment perpendicular to the field. This force manifests itself as a torque, because the magnetic moment originates from a spin angular momentum, and a cross product describes the effect of the magnetic force on an angular momentum. The resultant motion is a precession of the magnetic moment about the magnetic field direction at the Larmor frequency. The frequency of the precession depends on the strength of the nuclear magnetic moment and the magnitude of the magnetic field, as given above.

To affect nuclear Zeeman transitions, the magnetic field component of circularly polarized electromagnetic radiation applied at the Larmor frequency, $B_1(t)$, must have a component that is perpendicular to the direction of the external magnetic field. The circularly polarized magnetic field must also have the same sense of rotation as the nuclear precession. The Hamiltonian that describes the time-dependent interaction of the nuclear magnetic moment with $B_1(t)$ is $H_{B_1} = -\mu \cdot B_1(t)$. Using the expression for $B_1(t)$ at a frequency $w$ near or at the Larmor frequency and an initial phase $\phi$, that is, $B_1(t) = B_1[\cos(wt + \phi)t + \sin(wt + \phi)]$, the expression for the Hamiltonian for the time-dependent magnetic field interactions is $H_{B_1} = \hbar w, [\cos(wt + \phi)I_x + \sin(wt + \phi)I_y]$, where $w_1 = \gamma B_1$, and the operators $I_x$ and $I_y$ are the transverse components of the spin angular momentum operator. These operators can affect transitions of the nuclear spins between adjacent spin states.

2.4 Anisotropic Nuclear Spin Interactions

In NMR, nearly all observable properties are directly related to or described by a second-rank tensor, namely: diamagnetic and paramagnetic susceptibility, scalar (through-bond) coupling, dipolar (through-space) coupling, electric field gradient, and (chemical) shielding. Visualizing the spatial anisotropy of a second-rank tensor facilitates an understanding of many spectral features that are characteristic of NMRs in the solid state. Furthermore, a pictorial representation of an anisotropic spin interaction results in an automatic comparison of an experimental observable to the molecular architecture. The relationship is particularly clear for envisioning, for example, the variation of proton shielding as a function of hydrogen bond strength or the carbon shielding in strained ring systems. The electronic shielding of nuclei is a consequence of the interaction of the external magnetic field with the electrons of an atom or molecule. Hansen and Bouman depict a shielding surface as a representation for the traceless symmetric constituent of the shielding tensor. Resonance surfaces, which represent the NMR frequency directly, are similar to shielding surfaces. The purpose of this section is to explain resonance surfaces and to demonstrate their usefulness for understanding the anisotropic...
nature of the interactions of spins with their environment. Also, this will provide an avenue to understand the technique of magic angle spinning (MAS), which is ubiquitous in NMR studies of solids.\(^{(36,46,47)}\)

A Cartesian tensor of rank two is defined in every rectangular coordinate system by nine components, \(T_{kl}\), which transform under a rotation of the axis system into a new set, \(T'_{kl}\), according to Equation (1):

\[
T'_{ij} = \sum_{k=1}^{3} \sum_{l=1}^{3} R_{ik} R_{lj} T_{kl}, \quad (i, j = 1, 2, 3)
\]  

(1)

where \(R_{ik}\) and \(R_{lj}\) are the direction cosines contained in the rotation matrix \([R_{ij}]\).\(^{(48,49)}\) In a Cartesian coordinate system, the subscripts \(i, j, k,\) and \(l\) range from 1 to 3 and are assigned to the three Cartesian axes, as follows: \(1 = x, 2 = y,\) and \(3 = z\). The first subscript of a direction cosine refers to the new or rotated axis \((x'_1 = x_{\text{new}}, x'_2 = y_{\text{new}}, x'_3 = z_{\text{new}})\), and the second subscript refers to the old or original axis \((x = x_{\text{old}}, x_2 = y_{\text{old}}, x_3 = z_{\text{old}})\). The angle \(\theta_{ij}\) follows the same convention (e.g. \(\theta_{23}\) is the angle between the new \(y\)-axis, \(x'_2\), and the old \(z\)-axis, \(x_3\)). The two sets of Cartesian axes and the corresponding angles that connect them are illustrated in Figure 8.

Rather than discuss the nonsymmetric second-rank tensor \(T_{kl}\) as an abstract mathematical construct, here we will pictorialize the resulting analytical expressions that describe an observable directly affected by a particular second-rank tensor, namely the electronic shielding tensor.\(^{(50–52)}\) The description that follows is general and requires only a slight modification to incorporate the tensor of interest with its associated units of measurement. From this point forward it will be convenient to write the subscripts for tensor and vector components with the labels \(x, y,\) and \(z\) explicitly corresponding to the three Cartesian axes.

Each element of the shielding tensor \([\sigma_{ij}]\), Equation (2),

\[
[\sigma_{ij}] = \begin{bmatrix}
\sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\
\sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\
\sigma_{zx} & \sigma_{zy} & \sigma_{zz}
\end{bmatrix}
\]

(2)

determines, in part, a single component of the induced magnetic field vector in response to one of the components of the external magnetic field vector, \(B_{\text{ext}}\). The induced magnetic field is the response of a system of moving charged particles to a (typically large) static externally applied magnetic field. For example, the element \(\sigma_{xy}\) determines the magnitude of the \(x\)-component of the induced magnetic field vector, \(B_{x}^{\text{ind}}\), caused by the \(y\)-component of the external magnetic field, \(B_{y}^{\text{ext}}\) (see Figure 9). This has been expressed succinctly as follows, Equation (3):

\[
B_{x}^{\text{ind}} = \sigma_{yx} B_{y}^{\text{ext}} \quad (i, j = x, y, z)
\]

(3)

The general (nonsymmetric) second-rank Cartesian tensor (nine independent elements) can be written as the sum of a symmetric (s) and an antisymmetric (a) tensor, Equation (4):

\[
[\sigma_{ij}] = [\sigma_{ij}]^{s} + [\sigma_{ij}]^{a}
\]

(4)

The symmetric tensor can also be decomposed into a sum of two tensors, the isotropic (i) and the traceless symmetric tensor (ts), Equation (5):

\[
[\sigma_{ij}]^{i} = [\sigma_{ij}]^{s} + [\sigma_{ij}]^{ts}
\]

(5)

Thus, in some arbitrarily chosen Cartesian coordinate system (with axes labeled \(x, y,\) and \(z\)) we can write the

![Figure 8](image)

Figure 8 Matrix \([R_{ij}]\) is used to rotate a second-rank Cartesian tensor (e.g. \(\sigma_{ij}\)) from its original representation in the old (unprimed) Cartesian coordinate system to a new (primed) Cartesian coordinate system.

![Figure 9](image)

Figure 9 Electronic shielding tensor is defined in a Cartesian coordinate system. Each component of the induced magnetic field is given by \(B_{x}^{\text{ind}} = \sigma_{yx} B_{y}^{\text{ext}} \quad (i, j = x, y, z)\), where \(\sigma_{ij}\) is an element of the tensor matrix \([\sigma_{ij}]\) and \(B_{y}^{\text{ext}}\) is a component of the external magnetic field.)
following tensor decomposition, Equation (6):

$$\begin{bmatrix}
\sigma_{xx} + \sigma_{yy} + \sigma_{zz} \\
0 \\
0 \\
0
\end{bmatrix} \begin{bmatrix}
\sigma_{xx} + \sigma_{yy} + \sigma_{zz} \\
\sigma_{xx} + \sigma_{yy} + \sigma_{zz} \\
\sigma_{xx} + \sigma_{yy} + \sigma_{zz} \\
\sigma_{xx} + \sigma_{yy} + \sigma_{zz}
\end{bmatrix} = \sigma_0 =$$

$$\begin{align*}
\sigma_{xx} - \frac{1}{3}(\sigma_{xx} + \sigma_{yy} + \sigma_{zz}) \\
\sigma_{yy} - \frac{1}{3}(\sigma_{xx} + \sigma_{yy} + \sigma_{zz}) \\
\sigma_{zz} - \frac{1}{3}(\sigma_{xx} + \sigma_{yy} + \sigma_{zz})
\end{align*}$$

The tensor decomposition can be verified by adding corresponding elements from each of the constituents of the shielding tensor. For example, the shielding tensor element in the first column and second row is given by Equation (7),

$$\sigma_{xy} = 0 + \frac{\sigma_{xy} + \sigma_{yz} + \sigma_{zx}}{2} = \frac{-\sigma_{xy} + \sigma_{yz} - \sigma_{zx}}{2}$$

(7)

The traceless symmetric constituent of the shielding tensor can be diagonalized by a similarity transformation. The process of the tensor (matrix) diagonalization is identical to determining the traceless symmetric tensor elements in a Cartesian coordinate system coincident with the so-called principal axis system. The principal axis system is a peculiar Cartesian coordinate system wherein the traceless symmetric constituent of the shielding tensor is described by three elements, the so-called principal elements. These elements are labeled $\sigma_{11}$, $\sigma_{22}$, and $\sigma_{33}$, with the convention that $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$, and are located along the diagonal. The particular rotation matrix (determined from a similarity transformation) required to transform an absolute shielding tensor (described in some arbitrary Cartesian coordinate system) to the absolute shielding tensor in the principal axis system can likewise be applied to the isotropic constituent and the antisymmetric constituent of the shielding tensor. Three new elements are required to describe the antisymmetric constituent of the shielding tensor in the principal axis coordinate system. The antisymmetric principal elements, as they might be called, are labeled $\sigma_{12}$, $\sigma_{13}$, and $\sigma_{23}$.

Thus far we have accounted for six elements of a nine-element tensor. Since we have specified the principal axes as the coordinate system in which the tensor is described, the Euler angles that transform an arbitrary Cartesian coordinate system into the principal axis coordinate system account for the three missing elements. It will be useful to the reader of solid state NMR articles to show the complete description of the absolute shielding tensor in the principal axis system and some commonly used definitions that incorporate the principal elements. The complete description of the absolute shielding tensor described in the principal axis system can be written as follows, Equation (8):

$$\begin{align*}
[\sigma_0] & = \begin{bmatrix}
\sigma_{11} + \sigma_{22} + \sigma_{33} \\
0 \\
0 \\
0
\end{bmatrix} \\
\begin{bmatrix}
\sigma_{11} + \sigma_{22} + \sigma_{33} \\
\sigma_{11} + \sigma_{22} + \sigma_{33} \\
\sigma_{11} + \sigma_{22} + \sigma_{33}
\end{bmatrix} = \sigma_0 = \\
\begin{align*}
\sigma_{11} - \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33}) \\
\sigma_{22} - \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33}) \\
\sigma_{33} - \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33})
\end{align*}
\end{align*}$$

The average or isotropic shielding, $\sigma_{av}$, is very nearly equal to that which would be measured at a nuclear site in an isotropically tumbling molecule (because second-order terms are not included), Equation (9):

$$\sigma_{av} = 1/3(\sigma_{11} + \sigma_{22} + \sigma_{33})$$

A partial measure of the spatial anisotropy of the electronic shielding arising only from the traceless symmetric constituent of the shielding tensor is given by $\Delta \sigma$, which is (loosely) called the anisotropy and is defined as follows, Equation (10):

$$\Delta \sigma = \sigma_{33} - 1/3(\sigma_{11} + \sigma_{22})$$

Nonzero antisymmetric principal elements also account for spatial anisotropy of the shielding tensor and are not included in $\Delta \sigma$.

The difference between the largest shielding element, $\sigma_{33}$, and the average shielding, $\sigma_{av}$, is defined as delta, $\delta$, and is equivalent to two-thirds of $\Delta \sigma$, Equation (11):

$$\delta = \sigma_{33} - \sigma_{av} = 2/3 \Delta \sigma$$

Lastly, the axial asymmetry, $\eta$, which ranges from 0 (axially symmetric) to 1 (axially asymmetric or axially nonsymmetric) is defined by Equation (12),

$$\eta = \frac{\sigma_{22} - \sigma_{11}}{\delta}$$
The axial asymmetry is also a partial measure of the spatial anisotropy of the electronic shielding arising only from the traceless symmetric constituent of the shielding tensor.

Now that we have the general (nonsymmetric) shielding tensor broken down into its three constituent tensors, we can ask: What effect does each of the constituent tensors have on the resonance frequency of a nuclear magnetic moment? To answer this question we will find it convenient to write the induced magnetic field in terms of its spherical polar components. The induced magnetic field vector defined in Cartesian components, \( \mathbf{B}_{\text{ind}}^{\text{Cartesian}} = B_{x}^{\text{ind}} \mathbf{i} + B_{y}^{\text{ind}} \mathbf{j} + B_{z}^{\text{ind}} \mathbf{k} \), can be expressed in spherical polar components, \( \mathbf{B}_{\text{ind}}^{\text{Polar}} = B_{r}^{\text{ind}} \mathbf{e}_{r} + B_{\theta}^{\text{ind}} \mathbf{e}_{\theta} + B_{\phi}^{\text{ind}} \mathbf{e}_{\phi} \), by the following transformation, Equation (13):

\[
\mathbf{B}_{\text{ind}}^{\text{Polar}} = \mathbf{P} \cdot \mathbf{B}_{\text{ind}}^{\text{Cartesian}}
\]

where \( \mathbf{P} \) is the transformation matrix for the conversion of Cartesian to spherical polar coordinates. Explicitly, we have the matrix Equation (14):

\[
\begin{align*}
B_{r}^{\text{ind}} & = \sin \theta \cos \phi \sin \phi \cos \theta + B_{x}^{\text{ind}} \\
B_{\theta}^{\text{ind}} & = \cos \phi \sin \theta \sin \phi \cos \theta - \sin \theta \cos \phi B_{y}^{\text{ind}} \\
B_{\phi}^{\text{ind}} & = -\sin \phi \cos \phi 0 B_{z}^{\text{ind}}
\end{align*}
\]  

For an applied static magnetic field \( \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \) (in the direction \( \mathbf{e}_{r} \)) the induced magnetic field is given by \( \mathbf{B}_{\text{ind}}^{\text{Cartesian}} = -[\sigma_{ij}] \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \) in Cartesian components and \( \mathbf{B}_{\text{ind}}^{\text{Polar}} = - \mathbf{P} [\sigma_{ij}] \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \) in spherical polar components. It is from this last equation that the effects of \( [\sigma_{ij}]_{\text{Polar}} \), \( [\sigma_{ij}]^{\text{ts}} \), and \( [\sigma_{ij}]^{\text{as}} \) on the nuclear magnetic moment precession frequency and the nuclear relaxation rates can best be described. By expressing \( \mathbf{B}_{\text{ind}}^{\text{Cartesian}} \) in spherical polar coordinates and allowing \( \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \) to define the radial direction, \( \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \mathbf{e}_{r} = \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \), we will obtain components of \( \mathbf{B}_{\text{ind}}^{\text{Polar}} \) which are parallel \( (\mathbf{B}_{\parallel}^{\text{ind}}) \) or perpendicular \( (\mathbf{B}_{\perp}^{\text{ind}}) \) to \( \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \). The parallel component will increase or decrease the effective magnetic field directly and therefore affect the resonance frequency to first order. The perpendicular components will also affect the resonance frequency, but only to second order, and therefore to a much lesser degree (see Figure 10).

The interaction of molecular electrons, undergoing simple (diamagnetic) circular motion, with \( \mathbf{B}_{\text{ext}} \) is described by the isotropic constituent of the shielding tensor and results in an induced magnetic field that is (always) antiparallel to the external magnetic field.\(^{44} \) For any orientation of the external magnetic field in the Cartesian coordinate system in which the shielding tensor is defined, the perpendicular components of the induced magnetic field are always zero. The induced magnetic field is given by \( \mathbf{B}_{\text{ind}}^{\text{Polar}} = -\mathbf{P} \cdot [\sigma_{ij}] \cdot \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \), which results in the following expression, Equation (15):

\[
\mathbf{B}_{\text{ind}}^{\text{Polar}} (\theta, \phi) = -\sigma' \mathbf{B}_{\text{ext}}^{\text{Cartesian}}
\]

where, Equation (16),

\[
\sigma' = \frac{\sigma_{xx} + \sigma_{yy} + \sigma_{zz}}{3}
\]

The traceless symmetric constituent of the shielding tensor gives rise to an induced magnetic field with both parallel and perpendicular components relative to the external magnetic field. To first order in the resonance frequency of a nuclear spin, the spatial anisotropy of the shielding tensor is revealed by the parallel component. Additional (second order) spatial anisotropy of the shielding tensor arises from the transverse components. The equation \( \mathbf{B}_{\text{ind}}^{\text{Polar}} = -\mathbf{P} \cdot [\sigma_{ij}]^{\text{as}} \cdot \mathbf{B}_{\text{ext}}^{\text{Cartesian}} \) results in expressions for both radial and transverse components of an induced magnetic field. The radial component affects the resonance frequency to first order and is given by Equation (17),

\[
\mathbf{B}_{\text{ind}}^{\text{Polar}} (\theta, \phi) = \left\{ \begin{array}{l}
- \sin^{2} \phi \left( \sigma_{xx} - \sigma' \right) \cos^{2} \phi \\
+ \left( \sigma_{yy} - \sigma' \right) \sin^{2} \phi + \frac{\sigma_{xx} + \sigma_{yy} + \sigma_{zz}}{2} \sin 2 \phi \\
- \sin 2 \phi \left( \frac{\sigma_{xx} + \sigma_{yy}}{2} \cos \phi + \frac{\sigma_{xx} + \sigma_{yy}}{2} \sin \phi \right) \\
- \left( \sigma_{zz} - \sigma' \right) \cos^{2} \theta \end{array} \right\} \mathbf{B}_{\text{ext}}^{\text{Cartesian}}
\]

Although the antisymmetric constituent of the shielding tensor manifests itself very weakly in the NMR resonance frequency, it can play a significant role in the longitudinal nuclear spin relaxation rate.\(^{42} \) The antisymmetric constituent of the shielding tensor gives rise to an induced magnetic field consisting only of perpendicular components relative to the external magnetic field.\(^{53–56} \)

Thus far we have determined the contributions from the isotropic and the traceless symmetric constituents of the

---

**Figure 10** The resonance frequency of a nuclear spin caused by \( B_{\text{ind}}^{\text{eff}} \) is directly proportional to the net, effective magnetic field, \( B_{\text{ind}}^{\text{eff}} \), where \( B_{\text{ind}}^{\text{eff}} = \sqrt{B_{\text{ind}}^{\text{eff}}} + B_{\text{ind}}^{\text{as}} \). When \( B_{\text{ind}}^{\text{eff}} \gg B_{\text{ind}}^{\text{as}} \), the nuclear resonance frequency is affected by the transverse field, \( B_{\text{ind}}^{\text{as}} \), very weakly.
shielding tensor $[\sigma_{ij}]$ and $[\sigma_{ij}]^{\text{ts}}$ to the parallel component of the induced magnetic field, viz. Equation (18):

$$B_{\text{ind}}(\theta, \phi) = i B_{\text{ind}}(\theta, \phi) + i \sigma B_{\text{ind}}(\theta, \phi)$$  \hspace{1cm} (18)

The induced magnetic field affects several observables in an NMR experiment. We now turn to a quantitative examination of these effects.

The resonance frequency of a bare nucleus with spin 1/2 and placed in an external magnetic field is given by Equation (19),

$$\nu_{\text{bare}} = \gamma B_{\text{ext}}$$  \hspace{1cm} (19)

where $\gamma$ is the magnetogyric ratio, in units of Hz G$^{-1}$ (or radians T$^{-1}$). The presence of the moving electrons in the vicinity of the nucleus results in an induced magnetic field, which adds (vectorially) to the external magnetic field. Thus, in general, the effective magnetic field at the nuclear site is always less than $B_{\text{ext}}$. The effective magnetic field is given by $B_{\text{eff}} = B_{\text{ext}} + B_{\text{ind}}$, and the observed resonance frequency of the nuclear magnetic moment becomes (Equation 20)

$$\nu_{\text{obs}} = \gamma B_{\text{eff}}$$  \hspace{1cm} (20)

where $B_{\text{eff}} = \sqrt{(B_{\text{ext}} + B_{\text{ind}}(\theta, \phi))^2}$ to first order.

The isotropic constituent of the shielding tensor gives rise to an induced magnetic field that is always antiparallel to the external magnetic field. Hence, the effective magnetic field at the nuclear site is always less than $B_{\text{ext}}$. The effective magnetic field is defined in the principal axis system, Equation (21):

$$[\sigma_{ij}] = \begin{bmatrix} 20.0 & 50.0 & 0.0 \\ -50.0 & 20.0 & 0.0 \\ 0.0 & 0.0 & 100.0 \end{bmatrix}$$  \hspace{1cm} (21)

where the tensor elements are given in parts per million (ppm). For example, $\sigma_{xx} = 20.0$ ppm = (20.0/1000000). (Although this shielding tensor is antisymmetric, the antisymmetry does not affect the resonance surface because of the isotropic constituent tensor.) The resonance surface depicted in Figure 11 and all subsequent resonance surfaces were calculated and rendered using Mathematica. The symbolic language program AXIOM is also a useful mathematical tool for the investigation of second and higher rank tensors and is preferred by the author. The AXIOM system is marketed and distributed by the Numerical Algorithms Group, Ltd., Oxford, UK, and Numerical Algorithms Group, Inc., 1400 Opus Place, Suite 200, Downers Grove, Illinois, USA (Phone: (630) 971-2337, Fax: (630) 971-2706). The AXIOM commands can be obtained from the author, R.E. Gerald II, Argonne National Laboratory, 9700 S. Cass Ave., Argonne, Illinois 60439, USA.

The effect of the radial component of the traceless symmetric constituent of the shielding tensor on the resonance frequency of a nuclear spin can be viewed as a three-dimensional surface. The collection of points $[\nu_{\text{res}}(\theta, \phi), \theta, \phi]$, where $\nu_{\text{res}} = \nu_{\text{obs}} - \gamma B_{\text{ext}}$ (i.e., $\nu_{\text{res}} = \gamma/(B_{\text{ext}} + B_{\text{ind}}(\theta, \phi))^2 - \gamma B_{\text{ext}}$) results in a hyperboloid of two sheets. Again, with respect to the resonance frequency of the bare nucleus in the external static magnetic field ($\nu_{\text{bare}}$), those surface points designated by red represent frequencies that are lower, and those surface points designated by blue represent frequencies that are higher. Equivalently, when $B_{\text{ext}}$ intersects the hyperboloid at a point on the red surface the nucleus is...
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

**Figure 12** Resonance surface for the radial component of the induced magnetic field due to the traceless symmetric constituent of the shielding tensor. The surface is fixed to the molecular framework and results from the interaction of $B^{\text{ext}}$ (the applied static magnetic field) with the orbiting molecular electrons. The intersection of $B^{\text{ext}}$ with a red or blue surface causes the nuclear spin to resonate at a lower or higher frequency, respectively, compared to the resonance frequency of the bare nucleus. This surface corresponds to an axially symmetric shielding tensor. The intersection of the red and blue surfaces forms a conical node. The angle between the principal shielding axis (the direction of greatest electronic shielding) and the surface of the conical node is the magic angle, $\theta_m$.

shielded (the magnetic field is attenuated) and therefore resonates at a lower frequency compared to the bare nucleus. Similarly, when $B^{\text{ext}}$ intersects the hyperboloid at a point on the blue surface the nucleus is deshielded (the magnetic field is enhanced) and therefore resonates at a higher frequency compared to the bare nucleus. Figure 12 is a resonance surface depicting only the first-order effect of the traceless symmetric constituent of the same shielding tensor defined above, $[\sigma_0^{\text{sym}}]$, on the resonance frequency of a nuclear spin. Note the axial symmetry of the traceless symmetric resonance surface representing the axially symmetric ($\eta = 0$) tensor. Part of the spatial anisotropy of the electronic shielding tensor is due to the transverse induced magnetic fields that arise from the traceless symmetric constituent. However, the effect on the nuclear resonance frequency is very small and is not included in this analysis.

Figure 13 is also a resonance surface depicting only the first-order effect of the traceless symmetric constituent of the shielding tensor on the resonance frequency of a nuclear spin. However, in Figure 13 the shielding tensor is axially asymmetric ($\eta = 1/5$), and is defined in the principal axis system by Equation (22),

$$
[\sigma_0^{\text{sym}}] = \begin{pmatrix}
20.0 & 50.0 & 0.0 \\
-50.0 & 30.0 & 0.0 \\
0.0 & 0.0 & 100.0
\end{pmatrix}
$$

**Figure 13** Shielding surface similar to Figure 12, except that this surface corresponds to an axially asymmetric shielding tensor.

The antisymmetric constituent of the shielding tensor does not have a first-order effect on the resonance frequency of a nuclear spin. However, the magnitudes of transverse induced magnetic fields due to nonzero antisymmetric principal elements can be similar to the magnitude of the radial component of the induced magnetic field from the principal elements of a shielding tensor. In addition, part of the spatial anisotropy of electronic shielding is attributed to the transverse induced magnetic field when the antisymmetric principal elements are not zero. (The same can be said of the transverse magnetic fields determined by nonzero principal elements.) The small effects of induced transverse magnetic fields on the nuclear resonance frequency are difficult to measure. However, if the transverse magnetic fields are time dependent, then the antisymmetric principal elements can be estimated from measurements of spin-lattice relaxation rate constants (vide infra). From the perspective of the nucleus, a fluctuating induced transverse magnetic field is similar to $B_1$ fields generated by radiofrequency coils.

### 2.5 Averaging Spatial Anisotropy

The technique of magic angle sample spinning (MASS) is widely used to average the spatial anisotropy of nuclear spin interactions. A sample placed in a magic angle spinning (MAS) NMR probe is inclined at an angle of 54.74° with respect to $B^{\text{ext}}$ and continuously rotated at speeds up to 30,000 Hz. Under these conditions, the sample is analyzed by a multitude of high-resolution solid-state NMR experiments. Complete averaging of any anisotropic spin interaction that is mathematically described by a second-rank tensor occurs when the sample rotation frequency is several times larger than the frequency spread of the NMR spectrum for the static sample. A comparison of the achievable maximum spinning speeds with static NMR linewidths for a variety of solid materials...
shows that the MASS technique is frequently suitable for averaging the spatial anisotropy due to electronic (chemical) shielding. Samples with a high density of proton or fluorine nuclei (e.g. hydrocarbons, fluorocarbons, polymers) exhibit broad static NMR linewidths due to magnetic dipole (through space) coupling between nuclei, and such interactions are difficult to average by MASS. For those cases, a separate technique called high-power dipolar decoupling is used to reduce NMR linewidths. Details of the spatial averaging of second-rank tensors by MASS will be discussed in the context of electronic shielding, but they are equally applicable to other magnetic and electric spin interactions that are spatially anisotropic.

The isotropic constituent of the shielding tensor results in an induced magnetic field that is antiparallel to the external magnetic field, as discussed previously. For any orientation of the external magnetic field in the Cartesian coordinate system in which the shielding tensor is defined, the perpendicular components of the induced magnetic field are always zero. Since the induced magnetic field due to the isotropic constituent of the shielding tensor is independent of \( \theta \) and \( \phi \), rotation (of any type) has no effect. Therefore, the induced magnetic field component under MASS is given, as before, by (Equation 23)

\[
\langle B_{r}^{\text{ind}}(\theta, \phi) \rangle_{\text{MASS}} = -\sigma B_{\text{ Cartesian}}^{\text{ext}} \tag{23}
\]

where the angle brackets indicate an average of the angle \( \phi \) over the range \( (0^\circ \leq \phi \leq 360^\circ) \), and the superscript MASS signifies that the external magnetic field and the \( z \)-axis of the Cartesian coordinate system in which the shielding tensor is described always maintain an angle equal to \( \theta_m \) (vide supra).

As discussed previously, the traceless symmetric constituent of the shielding tensor gives rise to both parallel and perpendicular components relative to the external magnetic field. The so-called anisotropy and axial asymmetry of the shielding tensor are revealed by the radial (i.e. parallel) component. Additional anisotropy of the electronic shielding arises from the two transverse components. The equation for the time-dependent spherical polar component of the induced magnetic field due to the traceless symmetric constituent of the shielding tensor is obtained by replacing the angle \( \phi \) with the time-dependent angle \( 2\pi vt \) in the corresponding equation derived previously. The equation that follows describes \( ^{ts}B_{r}^{\text{ind}}(\theta_m, \phi) \), but is cast into a form (using the trigonometric identity \( A \cos(\phi) + B \sin(\phi) = \sqrt{A^2 + B^2} \sin(\phi + \zeta) \)), where \( \tan(\zeta) = A/B \) that will reduce easily under MASS to reveal its effect on the resonance frequency of a nuclear spin, Equation (24):

\[
^{ts}B_{r}^{\text{ind}}(\theta, \phi) = -\sin^2 \theta \left\{ (\sigma_{xx} - \sigma') \cos^2 \phi + (\sigma_{yy} - \sigma') \right. \\
\left. \times \sin^2 \phi + \left( \frac{\sigma_{xy} + \sigma_{yx}}{2} \right) \sin 2\phi \right\} - \sin 2\theta \\
\times \left( \frac{\sigma_{zz} + \sigma_x}{2} \right)^2 + \left( \frac{\sigma_{zz'} + \sigma_y}{2} \right)^2 \\
\times \sin(\phi + \zeta) - (\sigma_{zz} - \sigma') \cos^2 \theta B_{\text{ Cartesian}}^{\text{ext}} \tag{24}
\]

where the expression for \( \zeta \) is (Equation 25)

\[
\tan \zeta = \frac{\sigma_{xx} + \sigma_{yy}}{\sigma_{zz} + \sigma_{xy}} \tag{25}
\]

If we consider the effects of electronic shielding on the resonance frequency of a nuclear spin, under MASS, then the previous equation reduces to Equation (26):

\[
\langle ^{ts}B_{r}^{\text{ind}}(\theta_m, \phi) \rangle_{\text{MASS}} = \left\{ -\sin^2 \theta_m \left\{ \frac{\sigma_{xx} - \sigma'}{2} + \frac{\sigma_{yy} - \sigma'}{2} \right\} \\
- (\sigma_{zz} - \sigma') \cos^2 \theta_m \right\} B_{\text{ Cartesian}}^{\text{ext}} \tag{26}
\]

The radial component of the induced magnetic field due to the traceless symmetric constituent of the shielding tensor is directly proportional to the observed resonance frequency and can be transformed into the following result by noting that \( (\sigma_{xx} - \sigma') + (\sigma_{yy} - \sigma') = -(\sigma_{zz} - \sigma') \), Equation (27):

\[
\langle ^{ts}B_{r}^{\text{ind}}(\theta_m, \phi) \rangle_{\text{MASS}} = \left\{ -(\sigma_{zz} - \sigma') \frac{3 \cos^2 \theta_m - 1}{2} \right\} \\
\times B_{\text{ Cartesian}}^{\text{ext}} \tag{27}
\]

Thus, the effect of \( ^{ts}B_{r}^{\text{ind}}(\theta_m, \phi) \) on the resonance frequency of a nuclear spin vanishes when the \( z \)-axis of the Cartesian coordinate system in which the shielding tensor is described rotates about an axis tilted from the Cartesian by the magic angle, as illustrated in Figure 14. At the start of the rotation cycle, the laboratory frame is fixed and the \( z \)-coordinate of the tensor frame traces out the surface of the magic angle cone in Figure 14. The \( x \) and \( y \) coordinates of the tensor frame twist in this process such that their projections onto the laboratory \( x-y \) plane...
move in circular motions. That is, the projection of the $x$-coordinate of the tensor frame, for example, makes an angle $\phi$ with the $x$-axis of the laboratory frame, and $\phi$ varies from $0^\circ$ to $360^\circ$ during each rotation cycle. Therefore, the chemical shift interaction is averaged over $\phi$ in the MASS experiment, and $(b B_\text{ind}^\text{ts}(\theta, \phi))^{\text{MASS}} = 0$ for $\theta = 54.74^\circ$.

Thus far we have determined the contributions from the two constituents of the shielding tensor $[\sigma_{ij}]^\text{ts}$ and $[\sigma_{ij}]^\text{us}$ to the parallel component of the induced magnetic field under MASS, viz. Equation (28):

$$
(b B_\text{ind}^\text{ts}(\theta, \phi))^\text{MASS} = (b B_\text{ind}(\theta, \phi))^\text{MASS} + (b B_\text{ind}^\text{us}(\theta, \phi))^\text{MASS}.
$$

(28)

Under MASS, the isotropic constituent of the shielding tensor gives rise to an induced magnetic field that is always antiparallel to the external magnetic field. The effective magnetic field at the nuclear site is not modulated in magnitude or direction by rotating the Cartesian coordinate system in which the shielding tensor is defined. The observed NMR resonance frequency is constant and given by $\nu_{\text{obs}} = \gamma B^\text{ext} - \gamma \sigma B^\text{ext}$.

The average of $\langle b B_\text{ind}^\text{ts}(\theta, \phi) \rangle^{\text{MASS}}$ was previously shown to vanish under MASS. However, unlike $\langle b B_\text{ind}(\theta, \phi) \rangle^{\text{MASS}}$, which is not modulated under MASS, $\langle b B_\text{ind}^\text{us}(\theta, \phi) \rangle^{\text{MASS}}$ is modulated under MASS, even though the radial component produces a null average effect on the resonance frequency of the nuclear spin. This resonance frequency modulation manifests itself in spinning side bands in MASS experiments. Figure 15 shows the effect of spinning a sample at the magic angle at different spinning frequencies. An analysis of the spinning side band intensities determines the principal elements of the chemical shift tensor, which are directly related by a constant to the principal elements of the chemical shielding tensor.

The Hamiltonian that describes the through-space dipole–dipole interaction can be visualized in part by a second-rank tensor. In this case, the tensor is symmetric, that is, it has no antisymmetric component. The isotropic constituent of the dipolar interaction tensor is zero and, therefore, no resonance shift is observed under isotropic tumbling. The traceless symmetric constituent of the tensor is axially symmetric. Thus, the resulting resonance surface is always similar to the surface shown in Figure 12.

The quadrupolar Hamiltonian describes the interaction of the nuclear electric quadrupole moment with an electric field gradient. This interaction is described by a second-rank tensor as well. However, because of spatial symmetry, the quadrupolar interaction is described by a symmetric tensor and, therefore, results in a resonance surface with a spatial anisotropy similar to the surfaces in Figures 12 and 13. The isotropic shift is zero, except for cases where second-order effects, due to very large interactions, are significant. Engelhardt and Michel have provided a useful theoretical description of the quadrupole interaction and its effects on NMR spectra of quadrupolar nuclei.

2.6 Relaxation of Nuclear Spins

The description of the relaxation of nuclear spins is described in detail by Bloembergen. The previous analysis of electronic shielding can be expanded to include nuclear spin relaxation. Transverse and longitudinal fluctuating magnetic fields, regardless of origin, are the prerequisite for nuclear spin relaxation. Because the contribution to the induced magnetic field from the isotropic constituent of the shielding tensor is independent of $\theta$ and $\phi$, there is no magnetic field modulation due to molecular rotation at the site of the nucleus. Hence, the isotropic constituent of the shielding tensor plays no role in the relaxation of the nuclear spin.
Figure 15 MASS NMR spectra of $^{31}$P nuclei in solid dipalmitoylphosphatidylcholine recorded at different rotation frequencies. The rotation frequencies are indicated (in kHz). The static NMR spectrum (called a powder pattern) is characteristic of an axially asymmetric shielding tensor, from which the principal elements of the chemical shift tensor can be obtained. The principal elements can be obtained with greater accuracy from analyses of the spinning side band intensities. The position of the isotropic chemical shift is indicated by vertical dashed lines and does not change with rotation frequency. The series of spectra confirms that there is only one chemically distinct phosphorous species. Dipolar decoupling eliminated the dipolar interactions between protons and phosphorous nuclei.

However, molecular rotation does cause a time-dependent parallel component of the induced magnetic field that is due to the traceless symmetric and antisymmetric constituents of the shielding tensor. The rate at which an isochromatic nuclear spin ensemble loses phase coherence depends on the period of the molecular rotation, the axis of rotation, the rate of reorientation, and the anisotropy of the electronic shielding of the nuclear spins. For isotropic motion, the contribution to the transverse relaxation rate, $T_2^{-1}$, from the symmetric constituent is given by Equation (29),

$$\frac{1}{T_2} = \gamma^2 (B_{\text{ext}})^2 \frac{1}{15} S^2 \left( \frac{4}{3} \tau + \frac{\tau}{1 + w^2 \tau^2} \right)$$

where $S^2 = (\Delta \sigma)^2 (1 + (1/3)\eta^2) \omega^2 / 2\pi$ is the Larmor frequency (in Hz), and $\tau$ is the correlation time for the motion of the molecule; the other parameters have been described above.

The perpendicular components of the induced magnetic field also become time dependent upon molecular rotation; however, the second-order effect on the transverse relaxation rate is negligible. The time-dependent perpendicular components of the induced magnetic field do, however, affect the longitudinal relaxation rate to first order. The resulting longitudinal relaxation rate depends on the magnitude of the Fourier components of the changing transverse magnetic field near the nuclear spin Larmor frequency. For isotropic motion, the contribution to the longitudinal relaxation rate, $T_1^{-1}$, from the symmetric constituent is given by Equation (30),

$$\frac{1}{T_1} = \gamma^2 (B_{\text{ext}})^2 \frac{2}{15} S^2 \frac{\tau}{1 + w^2 \tau^2}$$

Because the antisymmetric constituent of the shielding tensor gives rise to an induced magnetic field, which is always perpendicular to the external static magnetic field, the second-order effect on the phase memory is very small. For isotropic molecular motion, the contribution to the transverse relaxation rate from the antisymmetric constituent is given by Equation (31),

$$\frac{1}{T_2} = \gamma^2 (B_{\text{ext}})^2 \frac{1}{3} A^2 \frac{\tau}{1 + w^2 \tau^2}$$

where $A^2 = (\sigma_{12}^2 + (\sigma_{13}^2)^2 + (\sigma_{23}^2)^2)$. The effect of the antisymmetric constituent of the shielding tensor on the longitudinal relaxation rate, however, is first order. For isotropic motion the contribution to the longitudinal relaxation rate from the antisymmetric constituent is given by Equation (32),

$$\frac{1}{T_1} = \gamma^2 (B_{\text{ext}})^2 \frac{2}{3} A^2 \frac{\tau}{1 + w^2 \tau^2}$$

Anet and co-workers have reported experimental evidence for a system in which $T_2 > T_1$. This unusual inversion of relaxation time constants is a direct consequence of a relatively large antisymmetric constituent of the shielding tensor in the system they studied.
3 SOLID-STATE NUCLEAR MAGNETIC RESONANCE INSTRUMENTATION

A modern NMR spectrometer consists of a superconducting magnet that generates a stable and homogeneous field; a radiofrequency console that provides control of frequency, duration, amplitude, and phase of pulsed radiofrequency energy output and input; a digital console that allows computer control of the radiofrequency console, and digitization of heterodyned NMR signals; and a computer that interfaces to the digital console for retrieval, processing, and storage of NMR data. Solid-state NMR spectrometers were historically distinguished from their solution-state counterparts by a larger magnet bore, higher power amplifiers, and a faster digitizer. Historically, a magnet bore diameter of 89 mm was desirable because it provided more room for large NMR probe heads of experimental design. The requirement for extra space in the magnetic field stemmed from the large high-voltage capacitors with high power handling capability that are required to generate large radiofrequency fields throughout the volume occupied by the sample. Short 90° pulses (1–2 µs) are required to record wideline and high-resolution solid-state NMR spectra for carbon or other low \( g \) nuclei (the so-called X nuclei). In addition, 300–400 W of pulsed radiofrequency power with less than 5% drop over a 100-ms period is needed for proton decoupling. A faster digitizer (\( \geq 1 \times 10^6 \) samples s\(^{-1} \)) is also necessary for recording spectral windows that are at least ten times larger than the spectral windows for solution-state studies. Modern solid-state NMR spectrometers are often based on solution-state machines, such that if a solutions spectrometer were purchased today, the solid-state capabilities could be added easily in the laboratory at a later time.

3.1 Magnet System

In the late 1940s and early 1950s, the magnetic fields available in the laboratory did not produce a magnetic flux that was uniform in space or constant over time. These magnetic fields were also quite modest when compared to magnetic field strengths generated by superconducting magnets that are common today. The early requirement for spatial uniformity of the magnetic field over the sample volume was technologically very demanding. A variation of less than 0.000001% is necessary to resolve coarse differences in the isotropic chemical shifts of protons in organic materials. The variation in magnetic field homogeneity available then was perhaps a few tenths of a percent, and it was considered nearly impossible to achieve the required homogeneity. In addition, the magnitude of the magnetic field over the sample volume was required to remain within the maximum variation in field homogeneity over the period of time that the experiment was conducted. For solid-state NMR applications, the requirements for homogeneity and field stability are not as demanding because resonance linewidths have a minimum dispersion of approximately 0.5 ppm, which cannot be removed by MASS. A magnetic field strength of 7 T is suitable for many solid-state NMR experiments. Higher fields (>11 T) are desirable for studies of quadrupolar nuclei because the spectra are simpler to interpret.

It was evident early on that the homogeneity of the magnetic field was of critical importance in resolving resonances that were different because of small variations in the electronic environment around the nucleus. For solid-state NMR, the spatial uniformity of the magnetic field over the sample volume should be moderately high, with a variation of approximately 0.000001% (0.01 ppm). This requirement is easily achieved without applying external field corrections in modern magnets. A temporal magnetic field variation of less than 0.02 ppm h\(^{-1} \) is typical for modern superconducting magnets and is suitable for many solid-state NMR experiments conducted over several days without field drift adjustments.

3.2 Spectrometer Console

A spectrometer console for solid-state NMR applications consists of a pulse sequence generator, high-power radiofrequency amplifiers, a fast switching device for routing high-power pulses to the probe and low-power NMR signals from the probe, and a receiver unit for amplifying, filtering, and digitizing the NMR signals. A simplified scheme for a solid-state NMR spectrometer apparatus is shown in Figure 16. The low-power CW oscillator (A) generates four quadrature radiofrequency outputs. Each output is gated on or off by the pulse

---

**Figure 16** Simple scheme of a solid-state NMR spectrometer apparatus. (A) Low power radiofrequency continuous wave (CW) oscillator; (B) pulse programmer; (C) high-power amplifier; (D) pass-through crossed diodes; (E) probe; (F) grounded crossed diodes; (G) preamplifier; (H) receiver; (I) digitizer; (J) computer; (K) magnet.
programmer (B) according to a program called a pulse sequence. The high-power amplifier (C) increases the peak-to-peak voltage \((V_{pp})\) of the radiofrequency pulse by a factor of about 200. The output of the amplifier (~200–300 \(V_{pp}\)) is directed to a three point junction via pass-through crossed diodes (D). The crossed diodes are made by connecting ten fast-switching diodes in parallel but alternating (crossed) polarity. At the junction, the radiofrequency pulses are directed to the probe (E) because the grounded crossed diodes (F) cause a high impedance at the junction as seen by the preamplifier (G). Effective routing of the high-power radiofrequency pulses to the probe and not the preamplifier requires that the length of each cable between the junction and the amplifier, probe, and grounded crossed diodes be 1/4 of the wavelength of the radiofrequency wave in the cable.\(^{65–68}\) The NMR signal (1–20 \(\mu V_{pp}\)) that proceeds from the excitation pulse follows the low impedance path to the preamplifier where it is amplified and passed to the receiver (H).\(^{65,70}\) The receiver heterodynes, filters, and amplifies the NMR signal before sending it to the digitizer (I). The digitizer samples the CW signal in quadrature at equally spaced intervals. The sampling rate is twice the frequency span that fully contains the NMR spectrum. The computer (J) is interfaced to the pulse programmer and the digitizer. It is used to upload pulse sequences to the pulse programmer and download data from the digitizer. The computer also processes and stores the NMR data.

### 3.3 Nuclear Magnetic Resonance Detectors

The selection of a probe for solid-state studies begins with a consideration of the systems that will be investigated (e.g. single crystals or powders, rigid or semi-rigid materials, gas/solid mixtures, etc.) and the experiments that will be performed (e.g. static or spinning, multinuclear observation, dipolar decoupled, etc.). Static, single-coil probes are the easiest to build and least expensive. For most solid-state NMR experiments, however, sample spinning will be desirable and required for recording high-resolution NMR spectra of powders. At a minimum, a solid-state spectrometer should be equipped with one spinning probe that can also be used in nonspinning mode for wideline experiments. The materials that are used to fabricate the stator, housing, rotor, and rotor caps of a MAS probe can be selected depending on the nuclei that will be studied. Probes for detecting NMR signals in solids require hard ceramic and plastic materials that can withstand high temperatures, and large centrifugal forces from spinning samples. These materials can produce background signals that can interfere with the samples under study. There are several combinations of ceramic and plastic materials that are used to build MAS probes. The materials are selected to minimize background signals from different nuclei, allow the highest spinning speeds, or give the largest temperature range for variable temperature studies. A combination of materials can be specified based on the type of studies that will be performed. Standard combinations are available for general-purpose probes. Table 1 includes materials that are currently used to fabricate stators, rotors, and caps for solid-state MAS NMR probes.\(^{71}\)

Static probes do not have rapidly rotating parts. This type of probe includes wideline, single crystal, and several imaging probes. The wideline probe is used to record broad NMR spectra. It features a very fast recovery time following a radiofrequency pulse for nuclear spin excitation.\(^{72,73}\) It is also designed to withstand 1–2 kW of pulsed (1–100 \(\mu s\)) and 100–400 W of continuous (1–100 ms) radiofrequency power. Probes for studying single crystals use a miniature goniometer to rotate the crystal within the NMR detector coil about an axis that is perpendicular to \(\mathbf{B}^{\text{ext}}\).\(^ {74}\) Solid-state imaging probes are similar to conventional imaging probes but are built to withstand higher radiofrequency power and are equipped with powerful (1000 G cm\(^{-1}\)) pulsed magnetic field gradients.\(^ {75}\)

Spinning probes are designed to rotate a sample contained in a rotor rapidly in one of three ways: at one angle (the magic angle, 54.74°), at several different angles sequentially, or at two angles simultaneously. A typical standard MAS probe is designed for a specific magnetic field strength and is capable of tuning to nuclei on the observe channel (or X channel) from 103Rh to 31P. The decoupler channel of such a probe is usually tunable over a much narrower frequency range that includes 1H and 19F nuclei. Broadband MAS probes provide the best performance at higher frequencies. If a considerable amount of work will be done at only one frequency, then a probe optimized for that frequency should be considered. The size of the rotor is also an important specification. For general use, a 5- or 7-mm-diameter rotor is common. However, if a substantial number of studies will require samples of limited quantity (a few milligrams), then a MAS probe with a 2.5-mm diameter rotor should be considered to maximize the filling factor (the sample-to-coil volume ratio) and, therefore, the sensitivity. The maximum spin rate of a probe is an important specification, but it should not be considered independently of rotor size and material. The rotors with the highest speed specifications are usually the smallest. If the amount of sample is not limited and the fastest available spinning speed not crucial for most experiments, then the larger slower rotors are more desirable. The temperature range for a standard spinning probe is –120 to +160°C. The range can be extended, –180 to +250°C, by a suitable change in design and probe material. A high-temperature probe is capable of reaching 650°C, while a low-temperature probe can spin at –267°C. A photograph of a MAS NMR probe head is shown in Figure 17. The outer diameter of the rotor is 7 mm and it is approximately 18-mm long. The probe is designed to operate continuously at a rotation frequency of 4 kHz.

Variable angle spinning (VAS) probes are similar in design to MAS probes. However, the spinning axis can be manually adjusted from 0° to 90° instead of a narrow range (±10°) near 54.74°. The angle is held fixed in a VAS probe throughout an experiment. The stator of switched angle spinning (SAS) probes can be computer manipulated via a rapid servo (in less than 50 ms) between two angles, usually 30° and 54.74°. In this probe, the coil follows the rotor, giving the optimal filling factor. The leads that connect to the movable coil require periodic replacement. The coil in a dynamic angle spinning (DAS) probe is stationary, and the spinning axis of the internal rotor can change to any orientation (360°) with respect to B0. The maximum flip time is 20 ms, with a position accuracy of 0.4°. The advantages of the DAS probe for experiments that require rapid changes between different spinning axes are high tuning stability (because the coil is fixed) and longer lifetime, in terms of number of flips. The primary disadvantage is that the minimum coil diameter is limited to the dimension of the rotor length, resulting in reduced filling factors and greater requirements for radiofrequency power to generate strong B1 fields. Double rotation (DOR) probes simultaneously spin two rotors, one within the other, to achieve high-resolution NMR spectra for quadrupolar nuclei. Stable rotation requires that a ratio of 1:5 be established for the spin rate of outer to inner rotors. The inner rotor contains the sample (100-µL volume), rotates at 6 kHz, and is tilted 30.12° with respect to the axis of the outer rotor. The outer rotor contains the spinning inner rotor, rotates at 1.2 kHz, and is tilted 54.74° with respect to B0.

Commercial spinning probes are fabricated from different materials, depending on the application, to eliminate or reduce specific background signals associated with the stator, housing, rotor, and rotor caps. For example, if a series of studies requires 29Si NMR, a rotor constructed from sapphire would produce less silicon background than one made of alumina. In addition, the stator assembly supports the radiofrequency coil, and the material it is made from will give broad background signals. A zirconia stator (95% ZrO2, 3.3% MgO, 1.5% HfO2, 0.06% SiO2, 0.03% Al) is common for general-purpose spinning probes and minimizes background signals from aluminum and silicon. An alumina stator (99.9% Al2O3, 0.2% SiO2) has a low dielectric loss and therefore is more suitable for applications such as CRAMPS (combined rotation and multiple-pulse spectroscopy) that require series of pulses with large field strengths. The higher thermal conductivity of alumina makes it the best choice for low-temperature studies. A silicon nitride stator has superior electrical properties (lowest dielectric loss and permittivity), making it the
SOLID-STATE NUCLEAR MAGNETIC RESONANCE

best choice for most applications, except those involving silicon and nitrogen. Even so, given the long $T_1$ time for silicon and the low natural abundance of nitrogen, this probe may still be suitable for some experiments involving these nuclei. The housing material is further removed from the detector coil, but it can still contribute to broad background signals. Its main purpose is to provide temperature control.

Probe materials are also selected for different operating temperatures. Macor (Al, Si, O, B, K, F) is used in probes that will detect carbon and proton signals with a maximum operating temperature below 160 °C. A Vespel (H, C, O, N) housing is useful for temperatures up to 300 °C, but it will provide a significant carbon background signal. The plastic Aurum (H, C, O, N) can be used to replace Vespel. A probe housing made of zirconia increases the temperature range up to 650 °C but is also more costly. Kel-f (p-chlorotrifluoroethylene) is a standard housing material that contains F, Cl, and C; however, the carbon signal is very broad because of C−F dipolar couplings. For fluorine studies, PEK (polyetherketone; H, C, O) can replace Kel-f and offers a larger operating temperature range (−180 to +225 °C). Glass dewars are commonly used for housings in probes for liquids but are rarely used in solid-state NMR probes because of the substantial background signal from Si, Al, Na, K, and other components of glass.

While the probe stator and housing can provide unwanted background signals that are usually broad, the rotor and rotor end caps can produce sharp background signals because these components, like the sample, are rotated rapidly and anisotropic spin interactions are averaged. In some cases a narrow background signal from a rotor can be used as an external reference for chemical shift and quantitation. In other cases, the signal from the rotor interferes with the desired spectral data and a different rotor material must be selected. Rotors are made from silicon nitride (Si$_3$N$_4$), sapphire (Al$_2$O$_3$), zirconia (ZrO$_2$), Macor (Al−Si glass), and some other materials. Silicon nitride rotors are the most expensive, about twice the cost of zirconia rotors, and are used for high spinning speeds. Sapphire rotors are about the same cost as zirconia rotors, are made of single crystals of Al$_2$O$_3$, and are translucent. They are useful for low-temperature studies, experiments that require the sample to be exposed to visible radiation, and NMR investigations of zirconium samples. Zirconia rotors are the most common, have high impact strength, can spin at speeds up to about 14 kHz, and are durable. Macor rotors are the least expensive, about 25% less than zirconia rotors, and are made of a glass material. These rotors are suitable for wet or air-sensitive samples. Samples of compressed gases (up to 50 atm) with solids or air-sensitive materials have been sealed in glass tube ampoules, placed inside rotors, and effectively spun. The low-density plastic CFR-PEEK (carbon-fiber-reinforced polyetheretherketone) is used for DOR rotors.

It is also important to consider the material that is used to cap the rotor. Rotors are usually made in either of two forms: a hollow cylindrical sleeve or a cylindrical closed-end tube. The hollow cylindrical sleeve requires a turbine cap to drive the rotor and a simple plug cap to seal the opposite end. For higher spinning speed probes, the plug cap can be replaced by a second turbine cap. The closed-end tube rotor only requires a plug cap if the sealed end is machined into a turbine; otherwise, a turbine cap is used. The plug or turbine caps are made from plastic materials, e.g. Kel-f, Vespel, and Aurum. Kel-f produces F, Cl, and C background signals and is useful over a limited temperature range (−20 to +70 °C). Vespel is a harder material with a larger temperature range (−270 to +80 °C) than Kel-f. Vespel can withstand higher spinning speeds compared to other cap materials; however, it produces C and H background signals. Aurum is similar to and can replace Vespel for fabricating caps that have a temperature range of −30 to +80 °C. Macor or other hard ceramic materials are also used; machined grooves in these caps accommodate soft O-ring seals. The Viton O-rings in these caps can operate in the range −150 to +250 °C but produce C and H background signals. Usually the plug or turbine cap limits the temperature of the experiment.

4 APPLICATIONS OF NUCLEAR MAGNETIC RESONANCE TO SOLIDS

There are numerous applications of NMR to solid materials in the physical, chemical, and biological literature. Three very different applications are presented below. They include examples in polymers, zeolites, and metals.

4.1 Wideline Nuclear Magnetic Resonance Spectroscopy of Polymers

The physical properties of solids and semisolids are partially determined by the temperature-dependent mobility of molecules. One-dimensional wideline NMR spectroscopic and relaxation data are diagnostic of different types of isotropic and anisotropic hindered molecular motions. Examples of molecular motions in solids that have been investigated by NMR include methyl group rotations, small-angle librations, 180° phenylene ring flips, helical rotations, and translations. In solids that are not dominated by an extended network of nuclear dipo- lar interactions, the temperature-dependent lineshape of a chemical shielding powder pattern can provide convincing evidence for well-defined anisotropic molecular
rotations. NMR spin-relaxation experiments can probe the motion of molecules or segments of molecules over the timescale $10^{-10}$ to 1 s. Polymers cover a range of materials with physical properties of solids and semisolids. Investigations of polymers by one-dimensional wideline NMR spectroscopy and nuclear spin relaxation experiments illustrate the specificity of information that can be obtained from a collection of easily implemented standard experiments. McBrierty and Packer have given details of the general application of solid-state NMR methods to polymer research. (78) More advanced two-dimensional NMR experiments provide specific details about molecular motions such as the exchange between crystalline and amorphous polymer phases and are discussed in detail by Schmidt-Rohr and Spiess. (79)

A simple one-pulse NMR experiment on polymer samples with a high concentration of magnetic nuclei with $I = 1/2$, e.g. $^{1}H$, $^{19}F$, and $^{13}C$, usually results in a very broad featureless spectrum. The broad line is the result of a complex extended network of nuclear spins that interact with each other via the magnetic dipole–dipole interaction. The linewidth and spin relaxation parameters $T_{1}$, $T_{2}$, and $T_{1p}$ can be measured as a function of temperature. These data provide information about molecular motion and phase transitions in solids. (80–82) For the case of dilute spins coupled to a network of abundant spins, it is found in many organic compounds, the $^{13}C$ NMR wideline spectrum can reveal chemical shift anisotropies, provided that the effect of the network of $^{1}H$ nuclei can be removed. This can be accomplished by acquiring the $^{13}C$ NMR signal while simultaneously irradiating the broad $^{1}H$ resonance with a radiofrequency magnetic field that is several times larger in magnitude than the $^{1}H$ linewidth. For solids with only a few distinguishable $^{13}C$ nuclei, the powder patterns for the different $^{13}C$ sites will show a temperature dependence that can partially, and sometimes fully, characterize the type of molecular motion (rotation, libration, reorientation) that takes place in the solid.

The $^{19}F$ NMR spectra of PTFE (poly(tetrafluoroethylene)), at different temperatures, recorded under conditions of homonuclear dipolar decoupling, provide an interesting example of two superposed chemical shielding powder patterns, as shown in Figure 18. (83) The broad asymmetric powder pattern recorded at $259 \degree C$ was attributed to the $^{19}F$ nuclei in crystallites imbedded in amorphous polymer. At high temperatures, the $^{19}F$ nuclei in the amorphous phase produce a narrow resonance because the mobility of these nuclei averages their anisotropic shielding tensors. Thus, the fractions of the polymer sample in the amorphous and crystalline phases were determined by decomposition of the observed spectra into a sharp symmetric resonance and a broad asymmetric powder pattern. At very low temperatures, the experimental spectra were decomposed into two identical powder patterns. This indicated that the chemical shielding tensors and, therefore, the chemical environments of the $^{19}F$ nuclei in the amorphous and crystalline phases were the same. More important, the temperature dependence of the transformation from an axially symmetric (at $28 \degree C$) to an axially nonsymmetric (at $14 \degree C$) tensor powder pattern for the crystalline component spectra can be fitted to a model of rotational diffusion about the polymer chain axis. Thus, the axially nonsymmetric chemical shielding tensor for the $^{19}F$ nuclei in the crystalline phase was made to appear axially symmetric by rotation of the $^{19}F$ nuclei about the chain axis. The homonuclear decoupling scheme in this study could not be continuous because the $^{19}F$ nuclei required simultaneous detection. A multiple-pulse decoupling sequence was used effectively to decouple the $^{19}F$ nuclei from each other via a series of discrete pulses between which the data points for the spectra were acquired.

4.2 Mobile Guests in Solid Host Material

Many interesting heterogeneous systems (e.g. gas/solid, and liquid/solid) are only partially composed of solids at ambient temperature and pressure. They are included here because the analysis of such systems requires understanding of interactions in the solid state and the
appropriate experimental techniques to average them. Xenon atom clusters trapped in the three-dimensional array of alpha cages in zeolite NaA provide a lucid example of how the local anisotropic cage environment determined by the host can influence the NMR spectrum of the guests. Solid-state NMR spectroscopy of zeolite hosts will not be discussed here. Engelhardt and Michel give a detailed description of solid-state NMR investigations of zeolite hosts. The wideline (static) $^{129}$Xe NMR spectrum of xenon atoms occluded in zeolite NaA is shown in Figure 19(a). Distinct broad peaks have been observed for xenon atom clusters ranging in size from 1 to 8 atoms per alpha cage. The combination of slow intercavity xenon atom exchange and large frequency shifts between the different $^{129}$Xe peaks makes it possible to resolve the different $^{129}$Xe peaks. However, the peaks do not have a Lorentzian lineshape; the approximately 10-ppm peak widths are not consistent with the measured spin–spin relaxation time constants of 15–40 ms and selective inversion of narrow regions of a single peak is possible. Therefore, the peaks could be a superposition of narrow Lorentzian resonances that have a range of positions covered by the width of the peak. The xenon atoms move rapidly within the alpha cages, even at low temperatures, so that the $^{129}$Xe nuclei in a cluster exhibit a resonance frequency that represents an average over the possible cluster configurations. The set of configurations that each cluster $^{129}$Xe may have is determined by the multidimensional potential energy surface in configuration space defined by $n$ interacting xenon atoms in the presence of the zeolite cage. For every configuration, each of the $n$ xenon atoms in the $^{129}$Xe cluster has an associated shielding tensor. The resonance frequency of the $^{129}$Xe nuclear spin of each atom in a configuration at any instant is determined by the orientation of its shielding tensor with respect to $B_{\text{ext}}$. As the configurations of the clusters interchange, the shielding tensor and its orientation for each xenon atom in the configuration changes, resulting in a different resonance frequency for each spin. The occurrence of each configuration of $n$ atoms in a $^{129}$Xe cluster is weighted by a Boltzmann factor and so too are the associated resonance frequencies for each member spin.

For individual clusters of xenon atoms occluded in zeolite NaA at room temperature, the rate of interconversion of configurations, including permutations of the xenon atoms among the $n$ particle coordinates for a single $^{129}$Xe cluster configuration, is fast compared to the nuclear precession coherence lifetime of the $^{129}$Xe spins. In other words, during the characteristic coherence dephasing time $T_2$ each xenon atom samples every particle position of every configuration, in the configuration space of the cluster, at least once. Therefore, an identical average resonance frequency is observed for each of the $n$ xenon atoms in a $^{129}$Xe cluster. Furthermore, the average resonance frequency of a $^{129}$Xe cluster is dependent on the orientation of the noncubically symmetric alpha cage in $B_{\text{ext}}$. For a powder sample of Xe/NaA, all orientations of the alpha cage are equally probable and each $^{129}$Xe cluster exhibits an inhomogeneous chemical shielding dispersion. Since the anisotropy of the alpha cage reveals the configuration...
weighted anisotropic xenon chemical shielding tensor, the MASS technique is suitable for reducing the width of the Xe\textsubscript{n} cluster peaks. Figure 19(b) shows the effect of MASS at 2 kHz on the same Xe/NaA sample used for the static spectrum (Figure 19a). The enhanced resolution afforded by MASS makes it possible to investigate binary mixtures of xenon and krypton atoms in NaA, as shown in Figure 19(c).

4.3 Metals

Nearly all metals have an isotope with a nonzero nuclear spin quantum number. Therefore, in principle, it is possible to record NMR spectra for these nuclei. In fact, a considerable amount of research on NMR properties of metals was conducted beginning in the 1950s. A monograph by Winter covers the fundamental properties of metals that influence their NMR spectra and provides several experimental results.\cite{86} This section broadly summarizes several of the important factors that determine the resonance frequency and spin-lattice relaxation time of the NMR signal.

NMR in metals was described in 1949 as producing narrow resonances comparable to those observed in liquids.\cite{87,88} While molecules in the liquid state tumble isotropically and in so doing, average out anisotropic spin interactions, atoms in a metal are fixed in the solid crystalline lattice and maintain a fixed orientation when placed in an external magnetic field. However, the conduction electrons rapidly move throughout the crystallite and produce an average fluctuating electronic environment at the nuclei. An estimate of the correlation time for a conduction electron moving from one unit cell to another is approximately $10^{-16}$ s; thus, the NMR nuclei with precessional periods of $10^{-7}$ to $10^{-9}$ s respond to an average electronic environment. That is, the conduction electrons average out the electronic shielding anisotropies that would cause inhomogeneous line broadening, and they move fast enough so that they do not shorten the lifetime of a nuclear spin in an excited state. This explains the narrow lines and lack of inhomogeneous broadening in NMR studies of metals.

Because the conduction electrons near the top of the Fermi distribution are not always spin paired, residual net magnetization from the magnetic moments of the electrons can exist at the nuclei. Knight used Fermi-Dirac statistics to predict the average net magnetization from the conduction electrons and showed that the nuclei would experience an additional field $K_B \delta^3$, where $K$ is the Knight shift and is usually positive. A measurement of the Knight shift can determine the number of conduction electrons per nucleus (i.e. metal atom) and their electronic wavefunctions. Hence, the Knight shift provides a measure of the coupling constant for the conduction electron/nucleus interaction.

Unpaired conduction electrons near the Fermi surface also contribute to magnetic field fluctuations at the nucleus. These fluctuating fields determine the spin-lattice relaxation time constants for the metal nuclei.\cite{89} The conduction electron relaxation effect for metal nuclei is weak because the frequency of magnetic field fluctuations is seven orders of magnitude higher than the nuclear Larmor frequency for typical laboratory fields. Figure 20(a) shows an NMR image of two forms of lithium metal in a battery. Both resonances exhibit a Knight shift near 260 ppm. The dendritic lithium was electrochemically deposited on the central carbon conductor. The two forms of lithium metal differ in Knight shift by 18 ppm. The $^7$Li Knight shift for an AlLi alloy is

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{image.png}
\caption{(a) NMR image of two forms of lithium metal in a battery (dendritic and counter electrode). Both resonances exhibit a Knight shift near 260 ppm, but differ from each other by 18 ppm. The dendritic lithium was electrochemically deposited on the central carbon conductor and has the weaker Knight shift. (b) The $^7$Li Knight shift for an AlLi alloy made by Reynolds Aluminum and used for jet airplane wings. The central conductor shown inside the cavity was the sample. A capillary tube containing 1 molal aqueous LiCl was placed next to the central conductor and used as a chemical shift reference. It also served to quantify the amount of Li that was detected in the surface layer of the sample.}
\end{figure}
shown in Figure 20(b). The sharp resonance is an external chemical shift reference of 1 molal LiCl (0 ppm). Although some of the first NMR experiments were conducted on magnetic materials, many NMR spectroscopists dismiss magnetic materials as too problematic for NMR analysis. In magnetic materials, the radiofrequency $B_1$ field experienced by the nucleus with an unpaired electron is enhanced by as much as $10^6$. The $B_1$ field produced by the radiofrequency coil couples with the magnetization created by the unpaired electron. The result is an effective $B_1$ field at the nucleus that can be dominated by the magnitude of the electronic magnetization. Thus, a weak radiofrequency $B_1$ field strongly couples to an electronic magnetic moment and the two fields add together and effect NMR transitions. Hence, the magnetic field experienced by the nucleus is largely the result of the electronic magnetic moment, which is made time-dependent by coupling to the radiofrequency $B_1$ field. Figure 21(a) shows the $^{57}$Fe NMR power saturation curve for the iron nuclei in a surface layer of a large iron rod that also functions as the NMR detector element in a toroid cavity probe. Figure 21(b) shows a representative $^{57}$Fe NMR spectrum of the rod. The NMR spectra were recorded at room temperature in a hyperfine field of 33.5 T.

5 PERSPECTIVE AND FUTURE DEVELOPMENTS

While NMR enjoys a high stature among spectroscopic methods because of the detailed information it can provide about composition, structure, mobility, quantity, and so on of molecules in all states of matter, its Achilles’ heel is lack of sensitivity. Sensitivity enhancement techniques that have been developed usually have restrictions preventing general use; nonetheless, they are critical to various applications. Some of these methods include higher magnetic field, hyperpolarized gases, and optical methods.

The development of hardware with enhanced performance continues for conventional probes by employing tailor-made materials. Cold probes offer additional sensitivity because they operate at cryogenic temperatures where the Johnson noise is reduced. Enhancements to the spectrometer console include more sensitivity from the preamplifier and receiver, greater expandability for additional transmitter as well as receiver channels, smaller footprints for self-shielding magnets, and portable NMR units.

Several applications of NMR methods for the analysis of a material resemble the approach taken by analytical chemists. The material is first separated into chemical components. Second, these components are identified. Finally, the relative amounts of the components are determined. Similarly, in multidimensional NMR experiments, the first step is to separate the resonance signals based on knowledge of the spin interactions in the material. Second, the NMR spectrum is recorded for specific spin interactions and used to identify a component. Finally, this spectrum can be analyzed quantitatively because there is a one-to-one correspondence between the signal intensity and the amount of the component of interest.

The analytical chemist is interested in determining the composition of an unknown substance in terms of molecular composition and quantity of each component. An elemental analysis provides the quantity of the elemental constituents of the unknown substance. This analysis usually requires that a portion of the sample be destroyed in the process. Mixtures require separation before individual analysis and identification of the constituents. The sensitivity of techniques generally available to the analytical chemist ranges from picograms of identified substance per gram of unknown to a fractional percentage of the same. Techniques exist for determining the molecular and
atomic structure. Morphology, including size and shape of particles and defects, twinning, and larger features of the bulk solid can also be important properties of the material that in part determine their function and efficacy in a process. The chemical state or environment (e.g. oxidation state) is an important property that is necessary to characterize a material. Sample issues that arise in an analysis include uniformity, quantity, stability to temperature, pressure, and so on, and physical properties. For example, a high vapor pressure at room temperature may preclude analysis of a material in ultrahigh vacuum by electron microscopy at room temperature. Many techniques are invasive and result in complete destruction of the sample. This can present a severe limitation if the sample is available only in limited quantities.

Existing techniques can provide complementary and often comparable information for solid-state NMR analyses. Some examples are X-ray diffraction of powders and single crystals, neutron scattering, synchrotron radiation scattering, electron microscopy, and rheology techniques such as dielectric and mechanical relaxation measurements. Unlike some of these techniques, analysis of solids by NMR is noninvasive and leaves the sample available for subsequent analysis by invasive methods. While analysis by solid-state NMR does require a minimum sample weight of tens of milligrams, compared to a few picograms for analytical methods such as atomic absorption spectroscopy, for cases where sample quantity is not severely limited, NMR can provide information that characterizes the sample in ways other than elemental composition. NMR allows the analyst to probe the sample selectively for information. For example, \(^1\)H NMR could provide detailed site information and distribution of the residual protons in a sample that was perdeuterated.

Selectivity and separation of spectral information is increasing through the growing repertoire of multidimensional methods that provide added spectral resolution by expanding the NMR information into additional dimensions. These dimensions can be associated with molecular translation, chemical bonding, or coordination number. Many times these additional dimensions provide information that is not accessible by any other technique, such as structure-function correlations. It is important to recognize that one of the principal advantages of NMR is that it not only provides an electromagnetic spectrum (over a narrow range of energies) of a system (as in other forms of spectroscopy), but that it also permits correlations between different parts of the spectrum. The correlations can establish incontrovertible proof of atomic connectivity through chemical bonds and proximity through space. In addition, correlations between specific parts of molecules and well-defined rotational or librational motions can be ascertained. In short, it is the extensive selection, separation, and correlation of spectral signatures that separates the NMR method from its competitors.

As in most analyses, however, a combination of complementary techniques proves most useful for complete resolution of a problem. As an example, the determination of the structure of a crystal by X-ray diffraction provides the number, type, and position of atoms and ions in the unit cell, but not their electronic connectivity nor mobility, which might be inferred. The application of NMR methods in conjunction with the X-ray data can provide convincing details of atomic connectivity, methyl group rotation, proton bonding (including hydrogen bonding), and trapped liquids. NMR offers the advantage of measuring the weak interactions between nuclei that allow molecular features to be correlated. Analyses of these correlations form a picture of atomic connectivity, molecular motion and function, and molecular arrangements from the atomic to the macroscopic.

There are 22 spin-1/2 nuclei other than hydrogen and carbon, some with more than one spin-1/2 isotope. Four of these, \( ^{15}N, \, ^{19}F, \, ^{29}Si, \) and \( ^{31}P \), have been of major importance in chemistry and nuclear magnetic resonance (NMR) and are the subject of an extensive literature. Many spin-1/2 nuclides have had more specialized uses, such as \( ^{3}H, \, ^{77}Se, \, ^{109}Ag, \, ^{115}Cd, \, ^{119}Sn, \, ^{125}Te, \, ^{129}Xe, \, ^{195}Pt, \, ^{205}Tl, \) and \( ^{207}Pb \). A few have been of limited use, generally due to poor sensitivity: \( ^{57}Fe, \, ^{89}Y, \, ^{103}Rh, \, ^{169}Tm, \, ^{171}Yb, \, ^{183}W, \, ^{187}Os \) and \( ^{199}Hg \).

Spin-1/2 nuclei generally produce sharp spectral lines, which may allow a wealth of fine structure from spin–spin coupling to be observed. This coupling, along with chemical shift information and dipolar coupling information (nuclear Overhauser effect (NOE)) are used in a variety of ways to obtain structural information and solve chemical problems.

After a brief discussion of analytical techniques, the history, experimental practices, physical properties, relaxation properties, chemical shift referencing, applications and literature references for each nuclide are presented.

1 INTRODUCTION

There are 22 spin-1/2 nuclei other than hydrogen and carbon, some with more than one spin-1/2 isotope. The group includes metals, nonmetals, metalloids and the noble gas \( ^{129}Xe \). They have two things in common, a spin quantum number of \( \frac{1}{2} \) and a literature that reflects 50 years of intense scrutiny by determined physicists, chemists and spectroscopists.

Four of these nuclei, \( ^{15}N, \, ^{19}F, \, ^{29}Si, \) and \( ^{31}P \), have been of major importance in chemistry and NMR and are the subject of an extensive literature. Many spin-1/2 nuclides have had more specialized uses, such as \( ^{3}H, \, ^{77}Se, \, ^{109}Ag, \, ^{115}Cd, \, ^{119}Sn, \, ^{125}Te, \, ^{129}Xe, \, ^{195}Pt, \, ^{205}Tl, \) and \( ^{207}Pb \). A few have been of limited use, generally due to poor sensitivity, including \( ^{57}Fe, \, ^{89}Y, \, ^{103}Rh, \, ^{169}Tm, \, ^{171}Yb, \, ^{183}W, \, ^{187}Os \) and \( ^{199}Hg \).

The spin-1/2 nuclei range in NMR sensitivity over seven orders of magnitude. Although several of the most sensitive nuclei could be observed by older instruments using the continuous-wave technique, most of the less sensitive nuclei had to await the development of powerful superconducting magnets and the introduction of the pulsed Fourier transform (FT) technique. The sensitivity improvement meant that NMR could be extended to nearly all elements in the periodic table. The resulting explosion of data and publications, combined with the early work, made possible the groundbreaking book “NMR and the Periodic Table”. This 1978 text serves as the model for most subsequent multinuclear NMR literature. Outstanding texts describing this field include “The Multinuclear Approach to NMR Spectroscopy” (1983), “NMR of the Newly Accessible Nuclei” (1983) and “Multinuclear NMR” (1987). More recently, the “Encyclopedia of NMR” (1995) contains several excellent reviews of individual nuclei. Biannual reviews
of the NMR literature have appeared in Analytical Chemistry, providing a convenient starting point for learning about particular applications.

What distinguishes spin-1/2 nuclei spectroscopically is the relatively long lifetime of the excited state. This long lifetime leads to well-defined, sharp spectral lines, which allow a wealth of fine structure to be resolved. The linewidth (measured in hertz, at the half-height of a peak) is inversely related to the lifetime of the excited state. High resolution analysis conditions (described below) are required to properly observe such sharp lines.

The basic tools of the NMR spectroscopist are chemical shift, spin–spin coupling and the NOE.

1.1 Chemical Shift
The nucleus experiences the effects of small magnetic fields in its immediate environment. Circulating electrons in chemical bonds produce a magnetic field at the nucleus that may either oppose or reinforce the much larger external field. When the local magnetic field opposes the external field, the nucleus is shielded. A shielded nucleus experiences a lower effective magnetic field strength and resonates at a lower frequency.

As a result, each type of nucleus in a molecule may have a slightly different resonant frequency. This frequency difference is called the chemical shift, because it arises from the chemical environment of the nucleus. The NMR spectrometer accurately measures the resonant frequency of all nuclei being observed in the sample in units of hertz (Hz), or cycles per second. Chemical shift is defined as the difference between the resonant frequency of a nucleus in one type of chemical environment and that of a reference nucleus, divided by the spectrometer observe frequency. Because the spectrometer observe frequency is usually in the megahertz range, whereas the chemical shift is usually in the hertz or kilohertz range, this ratio is expressed in parts per million (ppm). Note that chemical shift is independent of the external magnetic field strength, although the resonant frequency of any given nucleus depends directly on the external field strength. The chemical shift is a sensitive measure of the electronic environment of the nucleus. Much can be deduced about the chemical structure, nature of the bonding and electronic distribution of a nucleus from its chemical shift. An excellent discussion of chemical shift can be found in Abraham et al. [6]

1.2 Spin–Spin Coupling
The small magnetic field of the nucleus exerts an effect on neighboring nuclei called spin–spin coupling. The effect is transmitted through bonds via bonding electrons. A nucleus that experiences no coupling produces a single resonance line. For spin-1/2 nuclei, this line will be split into two lines by coupling with a neighboring nucleus. The stronger the coupling, the farther these two lines will be spread. Such coupling is known as J coupling. The coupling constant J is measured in hertz. Coupling constants can be negative or positive, although the appearance of the coupled lines in the spectra is independent of the sign. In a series of compounds where J-coupling decreases, for example, positive values may decrease to zero and then become negative. The absolute values of such a series will appear to decrease and then increase. Only the absolute value of J is measurable from the spectrum, but relative signs of couplings may be obtained. Because J represents the strength of the interaction between two nuclei, it is independent of the external magnetic field strength. The J-coupling pattern for spin-1/2 nuclei contains (n + 1) lines, where n equals the number of neighboring nuclei. Smaller couplings may come from more distant nuclei, sometimes several bonds away. Coupling patterns may be considerably more complicated due to an effect known as strong coupling, if the frequency difference between the coupled nuclei is not large compared to J. The magnitude of the coupling constant can give information about the stereochemical relationship between coupled nuclei. Three-bond couplings (denoted 3J) depend on the dihedral angle between the coupled nuclei. Three dependence is known as the Karplus relationship and it has been used (and abused) in stereochemical analysis for forty years. Most, but not all, nuclei have been shown to exhibit this relationship. Briefly, coupling is at a minimum when this angle is near 90° and a maximum when the angle is near 180°. Intermediate angles produce intermediate coupling constants. Spin–spin coupling is a powerful tool both for establishing connectivity through bonds between atoms in a molecule and for establishing stereochemical relationships.

1.3 Nuclear Overhauser Effect
The NOE is a complex phenomenon that has been discussed in a recent definitive text. The effect may be used to provide information on the spatial relationships of atoms in a molecule or to enhance the response of insensitive nuclei. The effect occurs only between nuclei that share a dipolar coupling, and dipolar relaxation makes a major contribution to the overall spin–lattice relaxation. The most common applications of the NOE are for the sensitivity enhancement of insensitive nuclei and for determining spatial relationships among the atoms in a molecule.

As a general rule the chemical shift range and the size of coupling constants increase as the atom gets larger. Thus the tritium nucleus, 3H, being small, has only a 20-ppm chemical shift range. Medium size nuclei such
as nitrogen and phosphorus have larger chemical shift ranges of hundreds of ppm. Large “heavy” nuclei such as platinum and thallium have chemical shift ranges of thousands of ppm. Coupling constants follow a similar trend.

1.4 Analytical Considerations for Spin-1/2 Nuclei

NMR spectroscopy is generally used for the identification and proof of structure of chemical compounds and quantitative determination of sample components. NMR also allows the study of a wide array of molecular details, including stereochemistry, molecular motion, intermolecular interactions, chemical equilibria, and many other applications. The technique is nondestructive, and highly selective, since the frequencies at which different nuclei are observed are extremely well dispersed throughout the radiofrequency spectrum. About 50 µM is required for efficient analysis. Signal averaging can reduce this quantity to 50 nM or less, depending on the complexity of the analysis. The less sensitive nuclei will require considerably higher concentrations. Samples may be gas, liquid or solid. Solid samples are usually dissolved, but both powdered and single-crystal samples may also be analyzed. Analysis time can be as little as five minutes, but dilute samples, insensitive nuclei or complex analyses usually require several hours, up to a realistic maximum of 48 hours. The precision of quantitative analyses is routinely ±5%; under rigorous conditions it can be ±0.1%.

There are a few important limitations of the technique. Low sensitivity is inherent to NMR. Even lower sensitivity will be encountered when there is a limited amount of sample, an insensitive nucleus is being observed, or a complex analysis is being performed. Pure compounds are usually required. Mixtures can often be analyzed, provided that each component of the mixture produces a unique NMR signal. Finally, background interferences become a limitation with very dilute samples.

The intensity of the NMR signal is directly proportional to the number of nuclei in the probe, making quantitative analysis straightforward. Like any analytical technique, quantification has more stringent requirements and demands closer controls than qualitative analysis. Both sample-dependent and instrument-dependent factors must be considered. Due to the low sensitivity of the technique, signal averaging is almost always required. This entails its own requirements.

A robust quantitative method must take into account the longitudinal relaxation time, \( T_1 \). The relaxation time is a measure of the time required for nuclei in the sample to return to their equilibrium distribution between ground state and excited state after an excitation pulse. It is important to note that, because the energy difference between ground state and excited state is so small, the normal kinetic energy of a room temperature sample is enough to keep the nuclei divided almost 50/50 between ground state and excited state. This is the main distinction between NMR spectroscopy and other spectroscopic methods such as ultraviolet spectroscopy where all species lie in the ground state until excited. In fact, the NMR signal arises from the small excess of nuclei in the ground state (the Boltzmann excess). Depending on the nuclide, the magnetic field strength and the temperature, the Boltzmann excess is of the order of one part in \( 10^5 \). In effect, this means that only 1/10 000 of the sample gives a signal. This is the principal reason for the insensitivity of NMR, and it is why signal averaging is almost always required. After an excitation pulse, the nuclei require time to re-establish their equilibrium distribution by losing the excitation energy to their surroundings. This exponential process is called spin-lattice relaxation. This process is characterized by a relaxation time constant, \( T_1 \).

Table 1 shows the percent recovery of magnetization after an excitation pulse as a function of \( T_1 \). As seen in Table 1, it requires five \( T_1 \) periods for the nuclei in the sample to recover 99.3% of their equilibrium distribution. However, if two 90° excitation pulses are separated by only one \( T_1 \) period, the second will generate only 63.2% as much signal as the first. To avoid this clearly nonquantitative response, a standard quantitative technique uses a waiting period or recycle time of five times the longest \( T_1 \) value among the nuclei being measured. Clearly, some information about the \( T_1 \) values of the nuclei in the sample is required. \( T_1 \) information can come from literature values, estimation, or preferably measurement. Depending on sample concentration, the \( T_1 \) values are easily measured by a variety of techniques. It is sometimes possible to add relaxation reagents to a sample to decrease \( T_1 \) by about an order of magnitude and shorten analysis time.

If decoupling is involved, the NOE may affect the intensity of different signals in a nonuniform way. The NOE can be suppressed by the addition of paramagnetic relaxation reagents or by a simple technique called inverse-gated decoupling. Inverse-gated decoupling uses

a waiting time of five $T_1$ periods with the decoupler off and then acquires signal with the decoupler on.

Standardization of analytical results is accomplished in the same way as other instrumental techniques. In addition to the requirement for high purity, NMR standards must produce a signal that can be distinguished from that of the sample and impurities. Standards may be internal, dissolved in the same solution as the analyte, or external, usually contained in an axially concentric tube. A calibration curve may be prepared with a series of concentrations of an external standard. The concentration of an analyte may be determined by adding a known amount of a pure standard to a measured volume of a solution with unknown analyte concentration. The number of equivalent nuclei represented by each sample peak and the standard peak must be taken into account.

The analytical conditions for high resolution spectra include two considerations: lineshape and acquisition time. Briefly, lineshape must be optimized in order to obtain the best resolution and signal-to-noise ratio. This is accomplished by adjusting the magnetic field homogeneity in a process known as shimming. The resolution of the observation (in hertz) is equal to the inverse of the acquisition time (in seconds). In other words, the longer the acquisition time, the higher the resolution. Long acquisition times are associated with lower signal-to-noise ratios.

2 THE MORE COMMONLY OBSERVED NUCLEI

2.1 Nitrogen-15

Nitrogen-15 has been a very useful nuclide, but its extremely low sensitivity made it difficult to observe. Modern high field instruments and special pulse techniques were required before $^{15}$N observation became practical. The low sensitivity arises from a low magnetogyric ratio (1/10 that of $^1$H) and low natural abundance (0.37%). An additional complication comes from the negative magnetogyric ratio, which leads to negative NOE effects. The negative NOE can lead to the complete loss of some signals when proton decoupling is employed.

The huge volume of literature can be accessed through a book, many periodic reports, and reviews.

2.1.1 Experimental Practices

The low sensitivity of $^{15}$N is a constant concern for the analyst. The normal techniques of using the largest possible sample and extensive signal averaging do not adequately address this problem. In addition, relaxation times may be rather long, increasing the time required for acquisition. In cases where proton decoupling is used, it is possible to lose the nitrogen signal entirely via negative NOE effects. These effects can be suppressed by addition of paramagnetic compounds (not recommended for basic nitrogens) or, preferably, by inverse gated decoupling. Under favorable conditions, the NOE may lead to a large sensitivity increase. There is a relatively simple technique that can greatly improve the sensitivity, although it requires that a proton be either bound to the nitrogen or at least bound to another atom (such as carbon) that is attached to the nitrogen. The technique is called polarization transfer. It is achieved by the use of a pulse sequence known as insensitive nuclei enhanced by polarization transfer (INEPT). This can provide up to a 10- to 20-fold increase in sensitivity for nitrogens with directly attached protons, and less for nitrogens with long-range coupled protons. In cases where such protons exist this is clearly the method of choice.

2.1.2 Physical Properties

The physical properties of $^{15}$N are listed in Table 2. Assuming that the low sensitivity problem can be overcome, $^{15}$N can be an excellent nucleus for studying chemical environments. There is a large chemical shift range of 1350 ppm. The currently accepted chemical shift reference is neat liquid nitromethane, set at 0.0 ppm. Ammonia and ammonium salts have also been used, but these suffer from large pH and medium effects.

2.1.3 Chemical Shift

Both nitrogen chemistry and nitrogen chemical shift are strongly influenced by the presence of a lone pair of electrons. This makes $^{15}$N useful for studying protonation effects, tautomerism and coordination effects. Protonation effects are particularly strong where a $\pi$ bonding system is involved. For example, the chemical shift of pyridine changes by 100 ppm upon protonation. Chemical shift ranges for nitrogen in aliphatic compounds are in the $\pm$200 to $\pm$400 range and are somewhat similar to $^{13}$C, although larger. The incorporation of an electronegative element on the nitrogen increases the chemical shift.

2.1.4 Coupling

Couplings to other nuclei are small, typically about half the size of the analogous carbon coupling. In the absence of lone pair contributions, coupling is linearly related to the percentage “$s$” character of the N–H bond. Thus, directly bonded protons show coupling constants of about $-75$ Hz, $-90$ Hz and $-135$ Hz, respectively, for sp$^3$, sp$^2$ and sp hybridized nitrogen. Such directly bonded protons may be subject to chemical exchange, so the couplings may be lost. Coupling constants may be used to study lone
pair effects, protonation, isomerization, stereochemistry and coordination. Couplings to carbon are again small. The range is about 0 Hz to \(-20\) Hz. Long range coupling constants are also small, but three-bond coupling values have been used in Karplus relationships, for example in peptides.

### 2.1.5 Relaxation

Relaxation of \(^{15}\)N is qualitatively similar to that of \(^{13}\)C, although nitrogen’s smaller magnetogyratic ratio leads to less efficient dipole–dipole relaxation. In general, this means longer relaxation times. Relaxation times \((T_2)\) range from about 15 s for amide nitrogens to 450 s in nitrobenzene, where the lack of attached protons greatly reduces dipolar relaxation.

### 2.2 Fluorine-19

Fluorine was one of the first nuclei to be observed by NMR. After a long history of significant applications, it continues to be one of the most useful. Due to its relatively high sensitivity it was possible to make observations on the early continuous-wave instruments. The early work is summarized in Dungan and van Wazer. \(^{13}\) Chemical shift values in the older literature must be used cautiously as both reference material and sign conventions have changed. A large chemical shift range and large coupling constants help make the fluorine nucleus a sensitive probe of chemical environments.

Chemical shift compilations have been published. \(^{14}\) Coupling constants have been reviewed. \(^{15}\) An excellent overview of fluorine NMR has been published. \(^{16}\)

### 2.2.1 Experimental Practices

Fluorine is easily observed, preferably with a probe optimized for fluorine detection, but also by simply retuning the proton probe. On some older instruments, the proton transmitter may have to be retuned or modified with an accessory to enable it to produce the required fluorine frequency. The large spectral width of possible

\(^a\) For an equal number of nuclei.

\(^b\) Product of relative sensitivity and natural abundance.

\(^c\) TMS, tetramethylsilane.
fluorine signals may require large data file sizes for high resolution, high sampling rates for the analog-to-digital converter and a wide frequency range for the excitation amplifier. These considerations become more important at higher field strengths. A broad background signal from fluorine-containing materials in the probe may be encountered. It is centered at about −120 ppm and is not usually seen unless very low concentration samples are observed.

2.2.2 Physical Properties

The physical properties of $^{19}$F are listed in Table 2. The large magnetogyric ratio and high natural abundance make $^{19}$F one of the most sensitive nuclei: 83% as sensitive as the proton. Fluorine has a wide chemical shift range of about 900 ppm, although most organic fluorides occur in a range of about 300 ppm. In much of the early literature trifluoroacetic acid (~76.6 ppm vs. CFCl₃) was used as an external chemical shift reference, but it has been replaced by external CFCl₃, which is assigned as 0 ppm. Perfluorobenzene, C₆F₆ (~163 ppm), has also been used as an external reference as well as a convenient, commercially available sensitivity standard.

2.2.3 Chemical Shifts

When fluorine is attached to carbon, the chemical shift will be from near zero to −275 ppm. Aromatic fluorides give chemical shifts between −90 and −150 ppm. Olefinic fluorides have a similar range, between −80 and −200 ppm. Approximate ranges for aliphatic fluorides are −200 to −300 ppm for monofluorides, −75 to −125 ppm for difluorides (>CF₂) and −50 to −100 ppm for the −CF₃ group. Positive chemical shifts occur when fluorine is attached to more electronegative elements than carbon, such as oxygen or the halogens. The chemical shift of F₂, for example, is 430 ppm.

2.2.4 Coupling

One of the outstanding characteristics of fluorine is that it couples so well to neighboring nuclei, leading to large coupling constants and unusually long-range coupling. This makes fluorine a sensitive probe of the local electronic environment. Coupling may also be transmitted through nonbonding electrons, producing rather unusual, so-called “through space” couplings, thus affecting atoms that are some distance away.

Geminal coupling (denoted $^{2}$JHF, indicating J-coupling through 2 bonds, between hydrogen and fluorine) to protons is large, often 5 to 10 times larger than the corresponding proton–proton couplings. Geminal couplings are in the range of 150 Hz to 300 Hz for aliphatic fluorides, but much smaller for olefinic fluorides, about 10 Hz to 80 Hz. Vicinal couplings ($^{3}$JHF) are frequently in the 10 Hz to 20 Hz range and may show a strong angular dependence. Karplus relationships are not useful as the normal transmission of the coupling effect, which is through sigma bonds, is complicated by transmission through nonbonding electrons. Long-range couplings may be quite extensive, e.g. 20 Hz for $^{3}$JHF in aromatic systems.

Couplings to carbon range from 160–400 Hz for directly bonded fluorines to 20–45 Hz for $^{2}$JCF. $^{3}$JCF and longer couplings are easily seen in a $^{1}$H-decoupled carbon spectrum.

Fluorine couples with all the other commonly occurring nuclides such as $^{31}$P and $^{15}$N. Couplings are large, as much as 1000 Hz to $^{31}$P and about 100–200 Hz to $^{15}$N. Longer-range coupling is common. Coupling to metals is also known, and may be quite large, up to thousands of hertz. Coupling through nonbonding electrons may provide some very long-range interactions.

2.2.5 Relaxation

Relaxation of $^{19}$F resembles proton relaxation. However, the fluorine nucleus is capable of relaxing by additional mechanisms, and this tends to make fluorine relaxation times somewhat shorter than the analogous proton relaxation times. NOE effects can be observed, making the $^{19}$F nucleus a useful probe of interatomic distances.

2.3 Silicon-29

The study of $^{29}$Si began before the nucleus could be observed directly. Proton spectra of silicon-containing compounds exhibit “satellite” peaks very similar to $^{13}$C satellite peaks, so Si–H coupling constants could be measured. Silicon itself is of medium sensitivity, and isotopically dilute at 4.7% natural abundance. As silicon polymers and other organosilicon compounds became more and more useful, an increase in the popularity of $^{29}$Si-NMR was natural. There is a large body of literature covering $^{29}$Si, including a general review,(17) and a chemical shift compilation.(18)

2.3.1 Experimental Practices

The analyst observing $^{29}$Si has several important considerations to take into account: background signals, negative NOE and long relaxation times. Because the NMR probe usually contains glass and other ceramics, there is a large, broad background $^{29}$Si peak at about −110 ppm to contend with. In many cases the peaks of interest have a higher chemical shift and the background signal is simply ignored. The judicious choice of observation window can minimize the appearance of the glass peak. It is also possible to record a “blank” spectrum (everything but the
sample, tube included) that can be subtracted from the spectrum of the sample. This of course doubles the analysis time. An elegant solution to this problem is to use one of the polarization transfer experiments such as distortionless enhancement by polarization transfer (DEPT). In this case, only silicon atoms that are coupled to protons will be observed. The glass background disappears. This technique is limited to proton-coupled silicon, provided that proton relaxation times are sufficiently long. It is not a good method for quantitative work.

Because $^{29}$Si has a negative magnetogyric ratio, the possibility of negative NOE enhancements exists. In a few cases, this can lead to the complete cancellation of the $^{29}$Si signal. In any case, this effect, which follows upon proton decoupling, leads to very nonquantitative responses. The negative NOE effects can be suppressed by the addition of paramagnetic materials such as Cr$^{3+}$ ion, which has the additional advantage of decreasing silicon relaxation times. However, the sample will be irretrievably contaminated, line widths will increase and there is the possibility of sample components reacting with the chromium. A cleaner way of suppressing unwanted NOE effects is to use the inverse-gated decoupling technique. The decoupler is applied only during the acquisition time. The decoupler is then turned off for a relatively long period (about 5 times the acquisition time or five times $T_1$).

A major impediment to $^{29}$Si analyses is the long relaxation time of the $^{29}$Si nucleus. Since signal averaging is required, the acquisition repetition rate is limited by how fast the silicon nuclei relax. The only way to avoid long acquisitions is to add paramagnetic materials as mentioned above. The addition of about 0.05 M Cr$^{3+}$ will reduce $^{29}$Si relaxation times by 50% to 90%, allowing faster recovery and more rapid pulsing. Quantitative work, therefore, usually relies on the combination of inverse-gated decoupling and addition of paramagnetics.

### 2.3.2 Physical Properties

The physical properties of $^{29}$Si are summarized in Table 2. With a natural abundance of 4.7% and a relatively large magnetogyric ratio, $^{29}$Si is moderately sensitive, rather like $^{13}$C. The chemical shift ranges about 400 ppm. Chemical shifts are referenced to tetramethylsilane (TMS), which also serves as reference for $^1$H and $^{13}$C.

### 2.3.3 Chemical Shifts

Although the total range of reported $^{29}$Si chemical shifts is about 750 ppm, most organosilicon compounds fall in the range of 40 ppm to $-220$ ppm. Chemical shift compilations are available. A major application of $^{29}$Si is the identification and structural characterization of siloxane polymers, for which extensive chemical shift data are available. Chemical shift data as well as additivity rules are available for polymeric silanes.

#### 2.3.4 Coupling

Due to the negative gyromagnetic ratio, most $^{29}$Si couplings have a negative value. Data summaries and theoretical aspects of Si–H coupling have been published. The values for $^{1}$J$_{SiH}$ are large, from about $-100$ Hz to $-350$ Hz. $^{2}$J$_{SiH}$ couplings are much smaller, in the range of $0$ Hz to $10$ Hz. Silicon–carbon couplings range from $-50$ Hz to $-100$ Hz for $^{1}$J$_{SiC}$ down to $0$ Hz to $20$ Hz for $^{2}$J$_{SiC}$. Silicon–fluorine couplings are positive and in the range of $100$ Hz to $400$ Hz. Silicon–phosphorus couplings are found to have approximately the range of $20$ Hz to $200$ Hz.

#### 2.3.5 Relaxation

It is important for the analyst to remember that $^{29}$Si relaxation times are long. A summary of relaxation times has been published. Typical values for most silicon atoms are 10–100 s. Unless paramagnetic relaxation reagents are employed, pulse repetition rates must be kept slow and analysis times correspondingly long. In addition, dipolar relaxation produces negative NOE effects as noted previously.

### 2.4 Phosphorus-31

Since the early days of NMR $^{31}$P has been one of the most useful and most-studied nuclei. With 100% natural abundance and a high magnetogyric ratio, $^{31}$P has a good sensitivity and is easy to observe. Most often observed in a broadband probe, phosphorus compounds generally produce clean, well-dispersed spectra with an abundance of coupling data. The importance of phosphorus in biological compounds has created intense interest in $^{31}$P-NMR spectroscopy, resulting in an enormous literature on the subject. The data are most easily accessed through the Handbook of $^{31}$P NMR Data, which contains chemical shift and coupling constant data for a large collection of all types of phosphorus compounds. Applications of $^{31}$P-NMR to organic chemistry, stereochemistry and structural characterization are presented in two dedicated monographs. A recent, brief, overview of the field is available.

#### 2.4.1 Experimental Practices

The observation of $^{31}$P is straightforward. It is usually accomplished in a broadband probe, with or without proton decoupling. The wide chemical shift range of more than 1000 ppm is accommodated with large data file
sizes. A typical $^{31}$P spectrum is acquired in the same way as a proton spectrum, with a wide spectral width and a tip angle less than 90°, with a repetition time of about one or two seconds.

### 2.4.2 Physical Properties
The outstanding physical characteristic of $^{31}$P is its sensitivity: only one order of magnitude less than the proton. This is a result of 100% natural abundance and a high magnetogyric ratio. $^{31}$P chemical shifts have a range of over 2000 ppm. 85% Phosphoric acid is used as an external chemical shift reference, at 0.0 ppm. Alternative chemical shift references are in use that avoid the problem of the broadness of the phosphoric acid line. Small differences between reported chemical shifts in the literature are common, due to matrix effects.

### 2.4.3 Chemical Shifts
Phosphorus chemistry is complex, with an enormous number of compounds having a wide range of coordination numbers and oxidation states. Most of the common organic phosphorus compounds give signals between 150 and $-100$ ppm.

### 2.4.4 Coupling
The phosphorus atom tends to have large couplings, easily visible in the proton or carbon spectra of organophosphorus compounds. Extensive compilations of coupling constants are available. Directly bonded ($^1J_{PX}$) couplings are exceptionally large, from 100 Hz to 1000 Hz for P–H coupling, $-50$ Hz to 500 Hz for P–C coupling and 500 Hz to 1500 Hz for P–F coupling. Geminal couplings ($^2J_{PX}$) are smaller: 0 Hz to 200 Hz for P–H coupling, 0 Hz to 100 Hz for P–C coupling and 0 Hz to 500 Hz for P–F coupling. Vicinal couplings ($^3J_{PH}$) are sometimes larger than the $^2J_{PH}$ values. The $^3J_{PH}$ coupling constants depend on the dihedral angle between the coupling atoms. These couplings conform to the normal Karplus relationship trends. Minimum values are found at angles near 90° and maximum values at angles near 180°. $^4J_{PH}$ values range from 0 Hz to 20 Hz. Very long-range couplings covering up to eight bonds are known. The values for such couplings are small.

### 2.4.5 Relaxation
Relaxation times for phosphorus compounds resemble those of protons, generally being in the 1 s to 20 s range. Organophosphate compounds usually have relaxation times in the 1 s to 10 s range. Matrix effects strongly affect these values. Compilations of relaxation times for phosphorus compounds are available.

### 3 THE LESS COMMONLY OBSERVED NUCLEI

#### 3.1 Hydrogen-3
Tritium is a rare isotope of hydrogen that has excellent NMR properties. It is the most sensitive nucleus: 21% more sensitive than $^1$H. The principal obstacle to its use is that it is radioactive, a β-emitter with a half-life of 12.5 years. Early work was hampered by low sensitivity instruments, which required large sample sizes. Modern instrumentation allows the analyst to observe extremely small samples of tritium, minimizing the hazards of the radioactivity. A definitive compilation of tritium NMR methods, data and applications was published in 1985. A 1995 review of more recent work is also available.

#### 3.1.1 Experimental Practices
The best source for experimental techniques in tritium NMR is ‘Handbook of Tritium NMR Spectroscopy and Applications’. A great deal of work has been directed to developing safe techniques for handling tritium-containing samples. Tritium is a “soft” β-emitter, meaning that the particle emitted has very little energy. Such particles cannot penetrate even a thin surface of plastic, so effective shielding is easily accomplished. Samples are usually contained in commercially available doubly enclosed tubes, which can safely contain the sample even if a tube breaks. Modern instrumentation and techniques allow analysis of low concentration samples, minimizing the hazards. However, the amount of tritium necessary for analysis is $10^7$ times that required for liquid scintillation analysis, a difference that illustrates both the sensitivity of scintillation counting and the general insensitivity of the NMR technique. Instrumentally, tritium observation closely resembles proton observation. The resonant frequency is 6.66% higher than proton, within the range of most ordinary proton observe channels. Conditions that are optimized for proton spectroscopy are also optimum for tritium observation.

#### 3.1.2 Physical Properties
With the highest magnetogyric ratio of any nucleus, tritium is the most sensitive: 21% better than the proton. Having almost no natural abundance, the tritium must be synthetically introduced into the molecule. Its chemical shift range is very similar to the proton, about 20 ppm. Chemical shift referencing is accomplished with tritiated TMS. In practice, normal TMS may be used, because the tritium/proton Larmor frequency ratio is known very accurately. Measuring the proton frequency of the reference material and multiplying by the Larmor frequency ratio gives the frequency of the tritium reference. This is referred to as “ghost” referencing.
3.1.3 Chemical Shift

All of the hydrogen isotopes have nearly identical nuclear shielding. This means that all three isotopes have nearly identical chemical shift scales and that the vast literature on proton chemical shifts (see Chemical Shifts in Nuclear Magnetic Resonance) can be applied to deuterium and tritium as well. Isotope effects are usually less than a few hundredths of a ppm. Replacement of a proton with a triton gives very clean spectra, with all coupling information preserved. Tritium may be introduced into a molecule in several ways, including catalytic tritiation. The products produced may differ from those expected, as the mechanism of the reaction is complex. This provides a clever method for mechanistic studies involving hydrogenation.

3.1.4 Coupling

Tritium coupling constants are nearly identical to proton coupling constants, being exactly 1.067 times larger. This similarity allows the use of existing literature on proton coupling constants in tritium NMR. A particularly interesting application allows the observation of couplings between protons with degenerate chemical shifts. For example, a CH3 singlet will become a doublet if one proton is replaced with a triton, revealing the T–H coupling. By calculation, the previously hidden H–H coupling constant can be determined.

3.1.5 Relaxation

Relaxation processes for 3H are the same as for 1H, in contrast to 2H, which relaxes by the quadrupolar mechanism. The extensive literature data on relaxation times for proton may be extended directly to tritium. In proton-decoupled spectra the prospect of an NOE must be taken into account for quantitative work. Qualitatively, the NOE can be used to study the proximity of a tritium atom to other protons in the molecule.

3.2 Iron-57

Iron has a spin-1/2 isotope, 57Fe. Observation of this nuclide is extremely difficult because of its low natural abundance and very low magnetogyric ratio. There is very little literature available. Only the Fe0 and Fe3+ oxidation states are diamagnetic.

3.2.1 Experimental Practices

The observation of 57Fe is straightforward. The sensitivity is slightly better than 13C, so acquisitions can be fairly rapid. Because the NOE is not usually an important factor, decoupling is simply done without any special precautions. 57Fe chemical shifts have a strong temperature dependence. Close temperature control is required. This temperature sensitivity has been exploited in dynamic NMR experiments, where organoselenium derivatives show coalescence temperatures about 50°C higher than in proton or carbon spectra. This brings the study of lower energy processes into the range of variable temperature probes.

3.3 Selenium-77

Selenium has been a useful NMR nucleus, with a relatively large body of data accumulated. A useful overall review provides a good starting point for the literature and there are several data compilations. Organoselenium chemistry is a large field, with many stereochemical applications including stereoselective synthesis and analysis of chiral compounds. Chiral derivatization reagents containing selenium have been used to detect chemical shift differences in diastereomeric adducts up to seven bonds away from the chiral site.

3.3.1 Experimental Practices

The observation of 77Se is straightforward. The sensitivity is slightly better than 13C2, so acquisitions can be fairly rapid. Because the NOE is not usually an important factor, decoupling is simply done without any special precautions. 77Se chemical shifts have a strong temperature dependence. Close temperature control is required. This temperature sensitivity has been exploited in dynamic NMR experiments, where organoselenium derivatives show coalescence temperatures about 50°C higher than in proton or carbon spectra. This brings the study of lower energy processes into the range of variable temperature probes.

3.3.2 Physical Properties

The physical properties of 77Se are listed in Table 2. The relatively high observe frequency of 57.3 MHz puts 77Se in the middle of the range of most multinuclear probes and the sensitivity is relatively good. The chemical shift spans a range of 3300 ppm. Chemical shifts are referenced to Se(CH3)2 in CDC13 at 0.0 ppm. An alternative reference compound is (C6H6)2Se2 in CDC13 with a chemical shift of 463 ppm. This compound has the advantage of being an easily handled solid with no objectionable odor.

3.3.3 Chemical Shift

Chemical shifts reflect both oxidation state and the electronegativity of substituents. Se5+ compounds are deshielded versus Se2+ compounds. For example, decreasing electronegativity of the substituents explains the chemical shift trend in the series of SeCl2 (1758 ppm),
SeBr₂ (1474 ppm) and SeI₂ (814 ppm). Oxidation state is reflected by the chemical shifts of Se(CH₃)₂ (0 ppm) and SeO(CH₃)₂ (812 ppm). Electropositive substituents produce shielded chemical shift values, as in H₂Se (−226 ppm).  

3.3.4 Coupling

Coupling in selenium compounds has been reviewed. Couplings are rather small. Directly bonded protons couple with selenium in the range of 40 Hz to 60 Hz. Coupling with directly bonded carbon gives values in the −40 Hz to −100 Hz range. Fluorine has one-bond coupling constants in the range of a few hundred hertz up to 1500 Hz. Longer range couplings in each case are about an order of magnitude less.

3.3.5 Relaxation

Relaxation time constants are in the range of 1 s to 30 s. There is not too much contribution from dipolar relaxation, so NOE effects are not too important. Pulse repetition rates can reflect the rather short \( T_1 \) values.

3.4 Yttrium-89

\(^{89}\text{Y}\) is 100% naturally abundant but suffers from a low gyromagnetic ratio. Long relaxation times make the nuclide difficult to observe. A review of available data has been published.

3.4.1 Experimental Practices

Lack of sensitivity is the main concern of the analyst. The long relaxation times are particularly difficult to overcome. The NOE may be used to enhance sensitivity if coupled protons are available.

3.4.2 Physical Properties

As mentioned, even though 100% abundant, \(^{89}\text{Y}\) has a low magnetogyric ratio.

3.4.3 Chemical Shift

Very few \(^{89}\text{Y}\) chemical shifts have been reported.

3.4.4 Coupling

Some coupling data have been obtained from satellite spectra. Coupling to carbon was measured as 12 Hz.  

3.4.5 Relaxation

Relaxation times for \(^{89}\text{Y}\) are very long, ranging from 1 min to 4 min. The nucleus relaxes by a dipolar mechanism, leading to a potentially very large NOE. The maximum NOE is a factor of −10.

3.5 Rhodium-103

Although \(^{103}\text{Rh}\) is 100% naturally abundant, it has one of the lowest magnetogyric ratios of all the spin-\(\frac{1}{2}\) nuclei. The sparse literature on rhodium chemical shifts and coupling constants has been reviewed. Rhodium NMR is not expected to make a significant contribution to rhodium chemistry.

3.5.1 Experimental Practices

The direct observation of rhodium presents a serious challenge to the analyst. Due to the low magnetogyric ratio, the observe frequency is often below the lower limit of tuning for a broadband probe. Most of the early work has been accomplished using double resonance techniques.

3.5.2 Physical Properties

\(^{103}\text{Rh}\) is 100% abundant, but extremely insensitive due to a low magnetogyric ratio. The chemical shift range of rhodium compounds is about 8000 ppm, referenced to rhodium metal.

3.5.3 Chemical Shift

Rhodium chemical shifts are temperature dependent. The chemical shift literature has been reviewed.

3.5.4 Coupling

Rhodium coupling is similar to the other transition metals. Coupling constants are somewhat smaller. Directly bonded coupling constants to proton are a few tens of hertz, to carbon about 30 Hz to 80 Hz, to fluorine about 60 Hz and to phosphorus about 80 Hz to 150 Hz.

3.5.5 Relaxation

Relaxation times for rhodium are similar to the other transition metals.

3.6 Silver-107 and Silver-109

Silver has two spin-\(\frac{1}{2}\) isotopes, \(^{107}\text{Ag}\) and \(^{109}\text{Ag}\) of nearly 50% natural abundance each. Most literature studies employ \(^{109}\text{Ag}\) because it is about 40% more sensitive. Silver ranks near the bottom of the group in sensitivity and does not have an extensive literature. Chemical shift scales for the two nuclei are nearly identical, while coupling constants of \(^{109}\text{Ag}\)
are expected to be about 15% larger than those for \(^{107}\text{Ag}\). Chemical shifts and coupling constants have been reviewed.\(^{(25)}\)

### 3.6.1 Experimental Practices

The low frequency of the silver resonance is at the extreme lower range of most broadband probes. The principal difficulty in silver observation is low sensitivity. Relaxation times tend to be rather long, limiting the pulse repetition rate. These two impediments can be overcome only by long analysis times.

### 3.6.2 Physical Properties

The outstanding physical property of these two nuclides is their low magnetogyric ratio, leading to very low sensitivity. The chemical shift range is about 270 ppm, referenced to the aqueous silver ion, \(\text{Ag}_{(aq)}^{+}\).

### 3.6.3 Chemical Shift

There is no extensive literature on chemical shifts for silver. Studies are often complicated by the fact that several species with complex equilibria may exist, making the technique even more difficult. Many of the chemical shifts are also highly concentration dependent.

### 3.6.4 Coupling

Few examples of silver coupling are known. Two-bond coupling to proton is about 10 Hz. Coupling to fluorine and phosphorus has been reported. The phosphorus–silver coupling constants were in the range of 500 Hz.

### 3.6.5 Relaxation

Relaxation times for the silver nucleus are long: about 50 s for aqueous silver ion and up to several minutes for silver salts in acetonitrile.

### 3.7 Cadmium-111 and Cadmium-113

Cadmium has been an interesting, if complicated, nucleus for NMR studies. There are two spin-\(\frac{1}{2}\) isotopes, \(^{111}\text{Cd}\) and \(^{113}\text{Cd}\). Both have about the same natural abundance and adequate sensitivity. Chemical shifts and coupling constants are essentially the same for both and have been reviewed.\(^{(25)}\) Cadmium complexes are rather labile and the situation may be complicated in aqueous solution. Only one resonance may appear even though several species such as dimers, trimers, etc. may be present. Cadmium has a useful application as a surrogate for zinc and calcium anions in biomolecular NMR studies.

#### 3.7.1 Experimental Practices

There are no special observational difficulties associated with cadmium. The negative magnetogyric ratio can lead to the expected negative NOE if proton decoupling is required. The possible loss of signal can be avoided using the techniques outlined in the \(^{15}\text{N}\) and \(^{29}\text{Si}\) sections. The sometimes long relaxation times of some cadmium compounds limit pulse repetition rates.

#### 3.7.2 Physical Properties

With a mid-range Larmor frequency and about 12% natural abundance, either isotope is relatively sensitive and easy to observe. The chemical shift range is nearly 1200 ppm. Chemical shifts are referenced to \(\text{Cd(CH}_3)_2\) at 0 ppm.

#### 3.7.3 Chemical Shift

Most alkyl-substituted cadmium compounds have chemical shifts in the range of 0 ppm to \(-400\) ppm. Inorganic cadmium salts are more likely to have chemical shifts in the range of 0 ppm to 600 ppm. Strong solvent dependence and complex equilibria are always possible.

#### 3.7.4 Coupling

Directly bonded cadmium–carbon coupling constants are in the 500-Hz range. Protons in alkyl cadmium compounds are long-range coupled at about 50 Hz. Directly bonded phosphorus couplings to cadmium are about 1300 Hz.

#### 3.7.5 Relaxation

Relaxation times for cadmium are long, often from 30 s to 60 s. Symmetrical compounds such as \(\text{Cd(CH}_3)_2\) have the longest relaxation times, in this case 60 s. Alkyl cadmium compounds with longer chains have relaxation times between 1 s and 10 s. In the case of proton decoupling, the potential for negative NOE is present.

### 3.8 Tin-115, Tin-117 and Tin-119

There are three spin-\(\frac{1}{2}\) isotopes of tin: \(^{115}\text{Sn}\), \(^{117}\text{Sn}\) and \(^{119}\text{Sn}\). The most sensitive is \(^{119}\text{Sn}\), closely followed by \(^{117}\text{Sn}\). \(^{115}\text{Sn}\) is about twenty times less sensitive. Most of the literature studies concern \(^{119}\text{Sn}\). Chemical shift scales are substantially identical for all three nuclides. Coupling constants show small differences, nearly negligible in the case of the two most sensitive nuclides, \(^{119}\text{Sn}\) is easily observed, and makes an excellent tool for the study of tin chemistry. Literature reviews and chemical shift compilations are available.\(^{(26,27)}\)
3.8.1 Experimental Practices

Observation of $^{119}\text{Sn}$ is straightforward, except for the negative magnetogyric ratio. The nuclide is sensitive, and relaxation times are not too long. Frequently, complex reactions with many intermediates and various products can be observed and characterized directly in the solution reaction medium. Close temperature control is required. Because $^{119}\text{Sn}$ has a negative magnetogyric ratio, the possibility of negative NOE enhancements exists. In a few cases, this can lead to the complete cancellation of the $^{119}\text{Sn}$ signal. In any case, this effect, which follows upon proton decoupling, leads to very nonquantitative responses. The negative NOE effects can be suppressed by the addition of paramagnetic materials such as $\text{Cr}^{3+}$ ion, which has the additional advantage of decreasing tin relaxation times. However, the sample will be irretrievably contaminated, line widths will increase and there is the possibility of sample components reacting with the chromium. A cleaner way of suppressing unwanted NOE effects is to use the inverse-gated decoupling technique. The decoupler is applied only during the acquisition time. The decoupler is then turned off for a relatively long period (about 5 times the acquisition time). Finally, the technique of polarization transfer may be employed in the pulse sequences DEPT or INEPT, provided that there are some protons coupled to the tin.

3.8.2 Physical Properties

The moderately high magnetogyric ratio and natural abundance of $^{119}\text{Sn}$ give it moderate sensitivity. The Larmor frequency of 111.9 MHz is in the middle range of a typical broadband probe. $^{119}\text{Sn}$ features a large chemical shift range of 5500 ppm. Chemical shifts are referenced to Sn(CH$_3$)$_4$.

3.8.3 Chemical Shift

The chemical shift ranges from 3000 ppm to $-2500$ ppm. Chemical shifts are very temperature dependent and may be highly solvent dependent. In general, an increase in coordination number means an increase in shielding which results in lower chemical shifts.

3.8.4 Coupling

Most $^{119}\text{Sn}$ coupling constants are large and negative. One-bond couplings to proton are in the range of $-1500$ Hz to $-2000$ Hz. Coupling to carbon is in the range of $-300$ Hz to $-500$ Hz. Coupling to fluorine is about $+1500$ Hz. Longer range couplings are known. Many tin couplings have been obtained from satellite peaks in proton and carbon spectra.

3.8.5 Relaxation

Tin relaxes in a manner similar to the other spin-$\frac{1}{2}$ nuclei. Relaxation times are usually a few seconds. If dipolar relaxation with nearby protons is possible, the analyst must take into account the possibility of negative NOE effects.

3.9 Tellurium-123 and Tellurium-125

There are two spin-$\frac{1}{2}$ isotopes of tellurium. $^{125}\text{Te}$ is so clearly the preferable of the two that nearly all of the literature reports are studies of this isotope. The chemical shifts and coupling behavior of the two isotopes are not significantly different. Chemical shift and coupling data have been reviewed.$^{28-30}$

3.9.1 Experimental Practices

The observation of $^{125}\text{Te}$ is straightforward. The sensitivity is more than twelve times better than $^{13}\text{C}$, so acquisitions can be fairly rapid. Because the NOE is not usually an important factor, decoupling is simply done without any special precautions. $^{125}\text{Te}$ chemical shifts have a strong temperature dependence. Close temperature control is required. As with $^{77}\text{Se}$, this temperature dependence has been exploited in dynamic NMR studies, where the coalescence temperatures of organotellurium compounds are even higher than the corresponding organoselenium compounds. This extends the range of dynamic processes that can be studied to lower energies. The higher coalescence temperatures for organotellurium compounds are more likely to be in the temperature range of variable temperature broadband probes.

3.9.2 Physical Properties

Tellurium-125 physical properties are listed in Table 2. With a relatively high magnetogyric ratio and 6.99% natural abundance, $^{125}\text{Te}$ is fairly sensitive. The chemical shift range of tellurium compounds is about 5000 ppm. Chemical shift compilations have been presented.$^{28-31}$ Chemical shift referencing is to Te(CH$_3$)$_2$ at 0 ppm or Ph$_2$Te at 422 ppm.

3.9.3 Chemical Shift

Chemical shift trends for $^{125}\text{Te}$ are similar to those for $^{77}\text{Se}$. Electronegative substituents produce high chemical shifts as in TeF$_6$ at 545 ppm and electropositive substituents produce low chemical shifts such as Te(CH$_3$)$_4$ at $-67$ ppm.

3.9.4 Coupling

Data on $^{125}\text{Te}$ coupling constants are not too abundant in the literature. Several reviews and compilations are
available. A convenient rule of thumb is that $^{125}$Te coupling constants will be about two to three times larger than the corresponding $^{77}$Se coupling constants. Some representative coupling constants are: directly bonded proton Te–H, about $-50$ Hz; directly bonded carbon Te–C, $-50$ Hz to $-100$ Hz; and directly bonded fluorine, Te–F, about $2500$ Hz to $3800$ Hz.

3.9.5 Relaxation

Relaxation time constants are in the range of 1 s to 30 s. There is not too much contribution from dipolar relaxation, so NOE contributions are not too important. Pulse repetition rates can reflect the rather short $T_1$ values.

3.10 Xenon-129

Xenon is unique among the noble gases for its NMR properties as well as its chemistry. As the only spin-$\frac{1}{2}$ nucleus among the noble gases, $^{129}$Xe is abundant, sensitive, and easy to observe. Much of what is known about xenon chemistry comes from $^{129}$Xe-NMR studies. Xenon is a heavy nuclide with a large chemical shift range and large coupling constants. $^{129}$Xe-NMR can be used as a sensitive probe of bonding and geometry in a wide variety of xenon compounds and complexes. The chemical shift and coupling constant literature has been reviewed.

3.10.1 Experimental Practices

The Larmor frequency of $^{129}$Xe lies in the middle range of a broadband probe. Sensitivity is good. Relaxation times are short, so pulse repetition rates can be rapid and analysis time short. The large chemical shift range requires large data sets for high resolution. Many less-stable xenon complexes require low temperature for stabilization. Special solvent conditions may also be required.

3.10.2 Physical Properties

The physical properties of $^{129}$Xe are listed in Table 2. Features are a large magnetogyric ratio and medium natural abundance. The chemical shift range spans over 7000 ppm. Chemical shifts are referenced to XeOF$_4$ at 0 ppm.

3.10.3 Chemical Shift

Xenon chemical shifts depend on the oxidation state of Xe: Xe$^0$ compounds give shifts between $-5460$ ppm and $-5331$ ppm, Xe$^{2+}$ compounds between $-3769$ ppm and $-574$ ppm, Xe$^{4+}$ compounds between $-662$ ppm and 595 ppm, Xe$^{6+}$ compounds between $-211$ ppm and 700 ppm, and Xe$^{7+}$ compounds 2077 ppm and higher. Temperature and other matrix effects are large.

3.10.4 Coupling

Many coupling constants between xenon and a wide variety of other nuclei have been reported. Xenon–fluorine couplings are particularly well studied. These coupling constants can be correlated with oxidation number: Xe$^{2+}$ has Xe–F couplings from 4800 Hz to 7600 Hz, Xe$^{4+}$ from 2400 Hz to 3800 Hz, and Xe$^{6+}$ from 95 Hz to 1400 Hz. Large temperature and solvent effects upon coupling constants have been observed.

3.10.5 Relaxation

Relaxation times for xenon compounds are short, usually less than one second.

3.11 Thulium-169

This nuclide is almost paramagnetic and there is little useful literature. There have been several solid-state studies published.

3.12 Ytterbium-171

Very little literature exists for this nuclide. Only the Yb$^{2+}$ oxidation state is diamagnetic, and compounds are not too stable. Coupling to fluorine has been reported as 120 Hz from satellite spectra.

3.13 Tungsten-183

Tungsten has a spin-$\frac{1}{2}$ isotope, $^{183}$W, but it has one of the lowest magnetogyric ratios of the group. This is somewhat compensated for by a moderate natural abundance. The lack of sensitivity has made this nuclide less interesting, as evidenced by the lack of literature. The available literature has been reviewed.

3.13.1 Experimental Practices

Very poor sensitivity is the main concern. The Larmor frequency is at the extreme low end of the typical broadband probe.

3.13.2 Physical Properties

In spite of the low magnetogyric ratio, a chemical shift range of 6000 ppm has been observed for $^{183}$W. Chemical shift referencing is to WF$_6$ at 0 ppm.

3.13.3 Chemical Shift

Chemical shifts depend on the oxidation state of tungsten. W$^{6+}$ compounds have chemical shifts from 0 ppm...
to 3000 ppm. Lower valent tungsten compounds have chemical shifts from $-1500$ ppm to $-3500$ ppm.

3.13.4 Coupling

Coupling constants for directly bonded protons are about 30 Hz to 80 Hz; for directly bonded carbon, 120 Hz to 190 Hz; for directly bonded fluorine, 10 Hz to 80 Hz; for directly bonded phosphorus, 200 Hz to 500 Hz.

3.13.5 Relaxation

Relaxation times for typical tungsten compounds are in the $1$ s to $10$ s range.

3.14 Osmium-187

Osmium has received very little attention due to low natural abundance and a very low magnetogyric ratio, the lowest of the spin-1/2 nuclei. The observe frequency is below the limit of a typical broadband probe.

3.14.1 Experimental Practices

Observation is quite difficult due to the very low Larmor frequency.

3.14.2 Physical Properties

Osmium is characterized by very low natural abundance and very low magnetogyric ratio.

3.14.3 Chemical Shift, Coupling and Relaxation Times

Coupling constants have been reported from satellite spectra. Coupling to protons is in the range of 16 Hz to 38 Hz. Coupling to carbon is from 80 Hz to 121 Hz. Relaxation times for $^{187}$Os are in the 1–25 s range.

3.15 Platinum-195

Platinum is an easily observed nucleus of moderate sensitivity. Much early work was done by observation of the $^{195}$Pt satellites in proton spectra. Along with the modern work, this has revealed a nucleus with an extremely wide chemical shift range and very large coupling constants. As expected, such a nucleus is quite sensitive to electronic effects as well as temperature and other matrix effects. Chemical shift and coupling constant data have been reviewed.

3.15.1 Experimental Practices

Observation of $^{195}$Pt is straightforward. Careful attention must be paid to matrix effects such as solvent, concentration, temperature and pH. The short relaxation times of platinum compounds usually allow rapid pulsing.

3.15.2 Physical Properties

The physical properties of $^{195}$Pt are listed in Table 2. The Larmor frequency is in the middle range, and the natural abundance is high enough for moderately high sensitivity. The chemical shift range of 13 000 ppm is one of the largest of the spin-1/2 nuclei. Pt(Cl)$_6$ is the reference compound, even though temperature and concentration effects are large. Coupling constants are large, often thousands of hertz. Relaxation times are rather rapid.

3.15.3 Chemical Shift

The large chemical shift range of $^{195}$Pt is spanned by a series of halogen compounds Pt(X)$_6$: for X = F, 11 800 ppm, for X = Cl, 4521 ppm, for X = Br, 2651 ppm, and for X = I, $-1528$ ppm. Chemical shifts are highly matrix dependent as previously mentioned. Generally, large chemical shift changes occur as ligands are changed, but changes in the ligands themselves have little effect on $^{195}$Pt chemical shift. For example, platinum alkyl complexes have similar chemical shifts, even with different alkyl groups.

3.15.4 Coupling

Platinum coupling constants are large. One-bond coupling to proton is from 100 Hz to 1000 Hz. Two-bond coupling is from 40 Hz to 90 Hz. Three-bond proton coupling is from 15 Hz to 50 Hz. Platinum–carbon one-bond coupling ranges from 600 Hz to 2000 Hz. Couplings to most of the other spin-1/2 nuclei have been reviewed.

3.15.5 Relaxation

Relaxation times of $^{195}$Pt are short. Typical $T_1$ values are from 0.3 s to 1.3 s. Linewidths up to 20–50 Hz are frequently encountered.

3.16 Mercury-199

Mercury has a spin-1/2 isotope, $^{199}$Hg. The advent of modern instrumentation made it possible to observe this nucleus rather easily. Chemical shift and coupling constant data have been reviewed.

3.16.1 Experimental Practices

Mercury is observed in the mid-range of most broadband probes. The sensitivity is adequate and no special techniques are required for detection at the millimolar level.

3.16.2 Physical Properties

With nearly 17% natural abundance and a moderately high observe frequency, $^{199}$Hg is in the middle range of
sensitivity. The chemical shift range is from about 0 ppm to $-2500$ ppm, referenced to external dimethylmercury, Hg(CH$_3$)$_2$. Although dimethylmercury is the accepted standard for chemical shift and all published values are referenced to it, the material represents an extreme health hazard. Contact can be fatal. It is easily absorbed through the skin and even through latex gloves. There is absolutely no place for this compound in the NMR laboratory. Alternative reference materials, including mercury salts, such as Hg(ClO$_4$)$_2$ or Hg(NO$_3$)$_2$, may be used, although the chemical shifts are concentration dependent.

3.16.3 Chemical Shift
Mercury compounds have a wide chemical shift range. Most organo-mercurials have chemical shifts from 0 ppm to $-1000$ ppm. A few compounds with electropositive substituents have positive chemical shifts such as Hg(SiH$_3$)$_2$ at 196 ppm. Most mercury salts have chemical shifts in the range of $-1000$ ppm to $-3000$ ppm.

3.16.4 Coupling
Mercury couples to proton in the 100–300 Hz range for two-bond coupling. Directly bonded carbon couplings are about 600–1800 Hz. Directly bonded mercury–phosphorus couplings are about 3700–5000 Hz. Two-bond couplings between mercury and fluorine have been measured to be 1200–2000 Hz.

3.16.5 Relaxation
Relaxation in mercury compounds is similar to other spin-1/2 nuclei, ranging from a few tenths of a second to a few seconds.

3.17 Thallium-203 and Thallium-205
By virtue of their sensitivity, $^{203}$Tl and $^{205}$Tl were among the first nuclei observed. The more abundant nuclide, $^{205}$Tl, is almost 14% as sensitive as proton, making it the fourth most sensitive of the spin-1/2 nuclei. Thallium is very well suited for NMR use, having an extremely large chemical shift range and extremely large coupling constants. Both the chemical shifts and coupling constants change dramatically when the thallium environment changes. Temperature, solvent, and other matrix changes, as well as substituent changes, produce some of the largest chemical shift and coupling constant changes of any of the spin-1/2 nuclei. This makes thallium one of the most sensitive known probes of the electronic environment. A wealth of literature was comprehensively reviewed in 1988.$^{(36)}$ A recent overview of the field is also available.$^{(37)}$ Thallium has been used as a surrogate for potassium and sodium in biological studies, because it is much more likely to show subtle effects in its environment.

3.17.1 Experimental Practices
As both thallium isotopes are relatively sensitive, observation of NMR signals is rapid and easily accomplished. Thallium concentrations in the millimolar and micromolar range are sufficient for obtaining spectra. Relaxation is rapid enough so that acquisition can proceed quickly. The very properties that make thallium so sensitive to environmental effects also cause some experimental difficulties. The temperature must be very closely controlled. Other matrix effects must also be carefully watched. The large chemical shift range must be accommodated by large data file sizes and large observe window widths. Although no special precautions must be taken, good laboratory practice is essential due to the toxicity of thallium compounds.

3.17.2 Physical Properties
The similarity of the NMR properties of the two nuclides is reflected in the similarity of the observe frequencies: 173.1 MHz for $^{205}$Tl and 171.5 MHz for $^{203}$Tl. The chief reason for the relative sensitivity between the two nuclides is their natural abundance: 70.5% for $^{205}$Tl and 29.5% for $^{203}$Tl. The total chemical shift range for thallium is about 7000 ppm. Thallium is commonly found in two oxidation states: Tl$^+$, with a chemical shift range of 3000 ppm, and Tl$^{3+}$ with a chemical shift range of about 7000 ppm. Thallium chemical shifts are extremely solvent dependent, and the temperature dependence is approximately 5 ppm per kelvin. The temperature dependence of thallium chemical shifts is so strong that chemical shift can be used to measure the temperature of the sample in the probe quite accurately. Chemical shifts are referenced to Tl(NO$_3$)$_3$. 

3.17.3 Chemical Shift
Thallium chemical shifts are strongly influenced by temperature, solvent and other matrix effects and the nature of the attached substituents. The substituent effects are extremely large. For example, the change in chemical shift from Tl(CH$_3$)$_3$ to Tl(CH$_2$CH$_3$)$_3$ is 130 ppm.

3.17.4 Coupling
As seen with thallium chemical shifts, thallium coupling constants are large. Directly bonded protons show coupling constants of about 6000 Hz, directly bonded carbons about 10 000 Hz or larger and directly bonded phosphorus about 3000 Hz. As expected from these
large values, long-range couplings are also quite large. Even five- or six-bond couplings to proton are in the range of 100 Hz, which is comparable to directly bonded carbon–hydrogen coupling. These extremely long-range effects make thallium an excellent probe of electronic environmental effects for mechanistic studies, solvation and ion-pair studies and the study of intermolecular effects.

3.17.5 Relaxation

The relaxation behavior of both nuclides is the same and, as expected, extremely sensitive to environmental effects. Typical relaxation times are in the range of a few seconds. Thallium relaxation times are very sensitive to the presence of paramagnetic species in solution, which can drastically reduce the relaxation time to the millisecond range.

3.18 Lead-207

The NMR behavior of $^{207}$Pb resembles that of $^{119}$Sn, but on a larger scale. The atom is larger, and both the chemical shift range and coupling constant range are correspondingly larger. With a moderately high positive magnetogyric ratio and high natural abundance, sensitivity is good. The chemical shifts of $^{29}$Si, $^{119}$Sn and $^{207}$Pb are related by linear equations. The literature on chemical shift and coupling constants has been reviewed.\(^26\); \(^27\)

3.18.1 Experimental Practices

With modern instrumentation, the observation of $^{207}$Pb is routine. Pulse repetition rates can be fairly rapid. A wide spectral width and large data sets are required for high resolution.

3.18.2 Physical Properties

The physical properties of $^{207}$Pb are listed in Table 2. The Larmor frequency is easily found in the middle range of broadband probes. With 22.6% natural abundance, $^{207}$Pb is rather sensitive. Lead spans an extremely large chemical shift range, from 10 000 to −6000 ppm. The large chemical shift range makes $^{207}$Pb very sensitive to temperature, solvent and structural environment. Chemical shifts are referenced to tetramethyllead, Pb(CH$_3$)$_4$.

3.18.3 Chemical Shift

Lead chemical shifts are similar, and most are linearly related to $^{119}$Sn chemical shifts. Electropositive substituents produce highly shielded chemical shifts, and in the normal fashion, electronegative substituents produce highly deshielded chemical shifts. Most four-coordinate lead compounds resonate in the range of 500 ppm to −800 ppm. Aromatic shieldings in the plumbocenes give chemical shifts in the −5000 ppm area.

3.18.4 Coupling

Lead couplings are large, and for the most part are linearly related to $^{119}$Sn coupling constants. Directly bonded protons give couplings of about 2000 Hz. Coupling to carbon ranges from −1000 Hz to 250 Hz. Coupling to other metals produces extremely large coupling constants. Coupling to $^{119}$Sn may be as large as −3600 Hz and coupling in some platinum compounds may be larger than 18 000 Hz.

3.18.5 Relaxation

Lead relaxation is very similar to the other spin-$\frac{1}{2}$ nuclei. In asymmetric compounds, linewidths of $^{207}$Pb spectra may be smaller at lower magnetic field strengths due to chemical shift anisotropy.

Two-dimensional Nuclear Magnetic Resonance of Small Molecules

Henrik Pedersen
H. Lundbeck A/S, Copenhagen-Valby, Denmark

1 Introduction

Since the first 2-D NMR experiment was suggested by Jeener in 1971, an enormous number of experiments have been designed and published. In the last 10 years the major development of new pulse sequences has been associated with biomolecular applications, but some of the sequences may also be very useful for structural elucidation of small molecules.

The 2-D NMR techniques have been pushed forward by the continuing developments in spectrometer hardware, including higher magnetic fields, improved probe heads, increased stability and performance of the electronics and the host computers. The incorporation of a PFG in one or three dimensions has given access to shorter acquisition times and spectra with less artifacts. Also, the development of mathematical calculation tools has facilitated the development of new 2-D NMR experiments. For example, the product operator formalism developed by Sørensen et al. makes it possible to calculate the fate of the magnetization at any point of a pulse sequence, and also helps in the design of new sequences.

Given the enormous number of possible 2-D pulse sequences, it is important for the chemist or spectroscopist, who wants to use 2-D NMR in structure elucidation or for spectral assignment, to be familiar with a relatively small number of experiments which can be employed on a more or less routine basis. The actual choice will be dependent on the available hardware and

the degree of desirable user interaction. A pulse sequence which is claimed to give better resolution and/or higher sensitivity may be very sensitive to improper setting of the pulse widths or $B_1$ inhomogeneity of the probe head. Also, relaxation phenomena may be a limitation for sophisticated long-lasting sequences.

The term “small molecules” here refers to organic molecules of $\text{MW} < 1000 \text{ g mol}^{-1}$. This will include many synthetic organic molecules, including drugs, but also oligosaccharides, peptides and nucleotides may fall in this category.

In this article, a basic knowledge of one-dimensional (1-D) NMR is presumed. Readers who want in-depth knowledge of the rather complex theory of 2-D NMR are referred to several excellent textbooks.$^{(3–5)}$ A very comprehensive overview with practical suggestions for many 2-D NMR experiments is given in the book by Braun et al.$^{(6)}$

Programming of pulse sequences from literature sources is not a trivial task, but the instrument vendors normally supply an extensive library of pulse programs, from which the user may choose his or her favorites.

This article will focus on relatively few and simple experiments, which alone or in combination can give appropriate structural information. This may inspire the user to put together a portfolio of experiments depending on the needs and degree of instrument sophistication available.

2 THE SECOND DIMENSION IN NUCLEAR MAGNETIC RESONANCE

2.1 The Birth of a Two-dimensional Spectrum

A 2-D NMR spectrum consists of a series of 1-D NMR spectra arranged in a rectangular matrix and Fourier transformed in both dimensions. The individual 1-D spectra are acquired with the same pulse sequence, and the only difference is the duration of a delay in the sequence. A schematic representation of the building blocks in a 2-D experiment is given in Figure 1.

During the preparation period, the spins of the observed nuclei are allowed to relax back to the z-axis (along the external field) and then receive the first pulse or pulses that serve to bring magnetization of the nuclei into the xy-plane. The variable (incremented time) follows as the evolution period in which chemical shifts and couplings evolve to give the wanted correlation types. Observable transverse magnetization is created during the mixing period by pulses and delays, and finally the signal is acquired during the detection period ($t_2$) as a free induction decay (FID). The effect of incrementing the evolution time through a series of spectra is that the signal intensity and phase vary. When these spectra are arranged as rows in a matrix, the resulting columns of the matrix define a new set of FIDs. Subsequent Fourier transformation of this set of FIDs gives the 2-D spectrum.

Depending on the experiment and the acquisition and/or processing method, the resulting spectrum may be phase sensitive with Lorentzian line shapes in both dimensions or it may be a magnitude spectrum. The latter takes up much less disk space and may be acquired in half the time, but the phase-sensitive spectrum gives better resolution. A magnitude spectrum may always be calculated from a phase-sensitive dataset, but not vice versa. In practice, phase-sensitive 2-D data are acquired by incrementing phases for each $t_1$ value by one of two methods, the States–Haberkorn–Ruben method$^{(7)}$ and the TPPI (time proportional phase increment) method.$^{(8)}$ The latter method relies on 90° step incrementation of the first 90° pulse and is used in the examples in this article.

2.2 Choice of Basic Parameters

The sweep width and spectrometer offset for a 2-D experiment are chosen from the corresponding 1-D spectra. If digital filters are available, the sweep width in the first dimension (referred to as $F_2$) can be set to focus on a minor part of the spectrum. If only analog filters are available, folding of signals from outside the sweep width around the spectral edges may occur. In the second dimension (referred to as $F_1$), cross peaks that lie outside the chosen sweep width in $F_1$ will always be folded.

In order to save hard disk space and to reduce processing time, it is an advantage to keep the resulting data matrix as small as possible. A $4K \times 4K$ matrix is the upper practical limit with state-of-the-art computers and software. For acquisition, the time requirement relies heavily on the number of individual serial files in the $F_1$ time domain. In most cases this can be kept as low as $128–256$. If a greater number of serial files are collected, the signal-to-noise ratio (S/N) will decrease because of relaxation during the prolonged evolution delay in the last FIDs. If very detailed information is required (e.g. coupling constants), it can be advantageous to restrict the sweep area to the correlation cross peaks of interest, rather than to increase the digital resolution for the whole spectrum.

If vendor-supplied pulse programs are used, suitable choices for other parameters are usually proposed by

---

**Figure 1** Schematic representation of a 2-D pulse sequence.
the vendor. A knowledge of 90° pulse lengths at the appropriate transmitter or decoupler power levels is, of course, necessary prior to setting up a 2-D experiment.

2.3 Processing

Prior to Fourier transformation, window functions are normally multiplied with the FID. A wide variety of functions are available, and the choice may have a great impact on the resulting spectrum. A popular window function is a shifted or unshifted sine-bell or squared sine-bell function.

The spectral resolution in $F_1$ can be enhanced by zero filling, i.e., transforming with a size greater than the number of increments. This will always lead to the formation of wiggles around the signals, but the level of wiggles may well be acceptable with two or four times zero filling. The newer generations of processing software offer the possibility of linear prediction in $F_1$ (9). The idea is that when the FID is cut even after a relatively short time in $F_1$, it contains all the needed information, and the further development of the FID may be calculated from the existing data. This means that linear prediction can be used as a kind of intelligent zero filling. If the S/N is not too low, linear prediction may be used routinely to double the number of data points, thus giving increased resolution or a shorter total experiment time. In fact, all the spectral examples shown in this article have been treated in this way.

2.4 Artifacts

Several types of unwanted peaks may occur in the resulting 2-D spectrum. Errors in the phase cycling scheme may give rise to unwanted coherences, and poor calibration of the pulse widths may give artifacts, especially when the full phase cycle is not obeyed. Wrong pulse lengths may in turn be a result of poor tuning and matching of the probe head.

Another phenomenon that is often encountered is the so-called $T_1$ noise, which appears as ridges in the vertical direction of the spectrum. The causes of this are all kinds of instrument instabilities, e.g., temperature variations, magnetic field disturbances and pulse instabilities.

Cosmetic improvements may be obtained by subtraction of rows that only contain noise peaks. This is particularly useful for magnitude spectra and spectra where all peaks of interest have the same sign.

2-D spectra of a symmetrical nature such as correlation spectroscopy (COSY), nuclear Overhauser enhancement spectroscopy (NOESY) and total correlation spectroscopy (TOCSY) may be symmetrized about the diagonal. The algorithm compares points which are mirror images around the diagonal and exchange the greatest value with the smaller value. The major drawback with the method is that although $T_1$ noise ridges will disappear, they will leave some false cross peaks.

2.5 Sensitivity Considerations

It is impossible to give general data for sensitivity and detection limits for 2-D NMR experiments, since they depend entirely on the performance of the actual instrument. For 1–2 mM solutions of small molecules, homonuclear correlations and inverse detected proton–carbon correlation experiments should be obtainable overnight or over the weekend on instruments with a basic frequency of 200 MHz or more. A way of testing the chance of success is to acquire a single serial file, process it and judge the S/N. With some experience the possibility of obtaining 2-D spectra may be judged from the 1-D spectra. In the examples shown in later sections, the sample concentrations and total experiment times are given.

If only very small sample amounts (micrograms) are available, the instrument vendors offer probe heads which give improved sensitivity for small sample volumes per unit of available sample.

2.6 Solvent Suppression

Several factors limit the dynamic range of an NMR spectrometer. Among these are the limited resolution of the available analog-to-digital converters (ADCs) and the performance of the amplification stages. Therefore, it is essential to reduce the signals arising from dominating solvent molecules. Selective irradiation of the solvent proton peaks with a weak radiofrequency (RF) field during the relaxation delay is fairly efficient, and in the case of water it may be invoked in all $^1$H detected experiments. If more solvent peaks are to be suppressed, an irradiation cycle where the irradiation frequency is moved from one peak to another with short intervals can be applied.

In heteronuclear correlation (HETCOR) experiments, water is the only solvent which is easily dealt with. For biomolecular applications, more sophisticated water suppression sequences may be employed, e.g., WATER-GATE (water suppression by gradient tailored excitation) and variants$^{10,11}$ and WET (water suppression enhanced through $T_1$ effects)$^{12}$ which also requires the use of shaped pulses.

3 INSTRUMENTATION

3.1 Magnets

All types of magnets can in principle be used for 2-D NMR, but in practice only superconducting magnets are
useful, because they combine high field and resolution with good magnetic field stability. Even very small changes in the magnetic field during a 2-D acquisition will give rise to major line artifacts ($t_1$ noise) in the $F_1$ dimension. The magnetic field stability is greatly influenced by magnetic disturbances in the vicinity of the magnet in the form of moving metallic objects. This can be partly compensated by the new generation of digital lock systems. Otherwise it may be necessary to perform demanding experiments during the night or other quiet periods.

As in 1-D NMR, the resolution obeys a linear relationship with the field strength whereas the sensitivity in theory increases with the square of the field strength. In practice, other hardware limitations (probe heads, transmitters, etc.) cause the exponent of the relationship for the sensitivity to be around 1.5. Although high field strengths give the best resolution and sensitivity, there are also some drawbacks. With increasing field, the time required for shimming (optimization of the field homogeneity) will rise and so will the need for tuning and matching of the probe head for the individual samples. In practice, 500 MHz can be considered the upper limit for easy operation when working with samples of different nature in different solvents. However, the problem with tuning and matching may be circumvented by the use of auto-tune probes, which have recently been introduced by the vendors.

### 3.2 Probe Heads

The part of an NMR spectrometer which has the greatest impact on instrument performance at given magnetic field is the probe head, and new designs have drastically improved the sensitivity of modern probe heads.

A wide variety of probe designs are available, and most of them allow for pulsing on two different nuclei at the same time (double resonance probes) or three different nuclei at the same time (triple resonance probes). The probes fall into two major classes: proton sensitivity optimized (often called inverse probes) and X-nucleus sensitivity optimized (often called normal probes).

A double resonance probe will normally contain two RF coils. The inner coil, which is closest to the sample, will afford the highest sensitivity because of the better coupling between RF coil and sample. The gain in sensitivity for a given nucleus on going from the outer to the inner coil is roughly a factor of two. While the highest possible proton sensitivity is of major importance in biomolecular NMR, small molecule applications will often, if enough sample is available, benefit from probes which are easiest to work with. Here the normal probes benefit from easier shimming and less sensitivity to tuning and matching of the coils. If sample spinning is used, the use of inverse probes will often give the so-called $Q$-modulations, which show up as antiphase spinning sidebands. These artifacts arise from poor symmetry of the sample tube and poor concentricity of the spinner turbine and sample with the inner coil, and, unlike in-phase spinning sidebands, they cannot be removed by shimming. However, most experiments will work on superconducting magnets without sample spinning.

To maintain sufficient chemical shift stability, temperature control of the probe head should always be applied. The target temperature should be set at least 5°C above the inlet temperature of the heating gas. This is especially important when decoupling sequences are employed, since these may give rise to substantial heating of the sample.

### 3.3 Pulsed Field Gradients

Although PFGs are the basis for magnetic resonance imaging and volume-selective NMR spectroscopy, the technique is relatively new in general solution-phase NMR. They do, however, represent a major step forward in reducing experiment time and spectral artifacts.

A PFG pulse in the $z$-axis direction will defocus all magnetization except for that aligned with the $z$-axis. The $z$-magnetization may then be brought back into the $xy$-plane by a 90° pulse, and is thus purified from unwanted magnetization. This is often referred to as purging gradients.

By using a set of two or more matched PFGs, the magnetization in the $xy$-plane may first be defocused, then manipulated by pulses and finally a PFG can refocus the magnetization of interest without bringing back magnetization arising from unwanted coherence. Hence the great advantage in using matched PFGs is that it is so efficient at selecting only wanted coherence that the need for phase cycling is circumvented, with the consequence that very short experiment times may be allowed, provided that the S/N is sufficient. Especially in indirectly detected heteronuclear experiments, the unwanted magnetization from protons attached to $^{12}$C is very efficiently suppressed compared with other methods. When PFGs are used for coherence selection in HETCOR, the ratios between the individual gradients are dependent on the X-nuclei involved.

Weak PFGs in the $z$-axis direction may be generated from the $z$-shim coil, but these are only sufficient for homonuclear experiments. To achieve the full benefit of PFGs, a dedicated probe head with a gradient coil and a gradient amplifier is needed. Although triple axis PFG accessories, which can give gradient pulses of all spatial orientations, are available, small molecule work will hardly benefit from more than single-axis gradient equipment.
3.4 Console and Computer

A prerequisite for doing 2-D NMR experiments is that the instrument can work in the pulse Fourier transform mode. Modern instruments are fairly flexible and may be configured for the wanted experiment by computer control. Older instruments are often less flexible and may require some rewiring, if for instance pulsing with the proton decoupler and simultaneous proton observation are required.

2-D NMR has been greatly facilitated by the development of fast computers working under UNIX or another modern operating system, which allows for fast matrix processing and display. In the case where the spectrometer is equipped with an old, slow computer, raw data may be transferred to a modern computer and processed, plotted and displayed from there with an appropriate software package.

4 HOMONUCLEAR CORRELATION EXPERIMENTS

4.1 The Correlation Spectroscopy Experiment and Variants

The COSY experiment\(^{13}\) is one of the most popular 2-D experiments in NMR, and it exists in numerous variations. The resulting 2-D NMR spectrum (Figure 2) of the antipsychotic drug sertindole (CAS 106516-24-9)\(^{14}\) shows the 1-D spectrum on the diagonal and \(J\)-coupling correlation as off-diagonal cross peaks. The pulse sequence and phase cycle with optional PFGs are given in Figure 3. The resulting spectrum is in magnitude mode. The second 90° pulse may be changed to 45°, and at some expense of sensitivity this will narrow the diagonal, and thus ease the interpretation of tightly coupled spin systems. With the PFG version a total acquisition time of less than 5 min may be achieved, provided that enough sample is available.

If enhanced spectral resolution is required, double quantum filtered correlation spectroscopy (COSYDQ) (Figure 4)\(^{15}\) may be the experiment of choice, since this may be performed in the phase-sensitive mode without giving dispersive diagonal signals. The double quantum filter serves to remove noncoupled signals (singlets) from the diagonal. Especially the PFG version\(^{16}\) of this experiment (Figure 5) is effective in reducing singlet solvent lines. This is shown by the PFG/COSYDQ spectrum of sucrose (CAS 57-50-1) in 90% water (Figure 6).

In the case where the size and the sign of proton–proton coupling constants are wanted for complicated spin systems, a variant called E.COSY (Exclusive Correlation Spectroscopy)\(^{17}\) gives simplified cross peaks, where a given multiplet component correlates selectively with only two components of its \(J\)-coupled proton, and not with all of its components as is the case in a normal COSY experiment. Since different spin system order requires different phase cycles, the experiment is hardly useful for routine work. In less demanding cases a COSY experiment where the second pulse is set to 45° instead of 90° may give a similar result (COSY-45).
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

The TOCSY or HOHAHA (homonuclear Hartmann–Hahn)\(^{[16,18]}\) is probably the most popular member of the family of so-called spin-lock experiments. After the initial 90° pulse, a strong field is applied which serves to lock the magnetization and avoid evolution of individual spins. The effect is that protons in a common coupling network will all correlate if the duration of the spin-lock field is sufficiently long. A COSY-like spectrum may, on the other hand, be obtained if the spin-lock time is short enough. This may give an advantage since the TOCSY cross peaks are in phase. A spin lock of 10–20 ms will give COSY-like spectra and 40–100 ms will correlate more spin systems in a coupling network. The spin lock may be generated in several different ways, but a very common way is to use the composite pulse train MLEV (Malcom Levitt)\(^{[18]}\) surrounded by trim pulses.

The TOCSY sequence with optional PFGs is shown in Figure 7. The details of the MLEV cycle are not given because of its complexity. On older instruments the hardware must be configured in the inverse mode and the power of the preparation pulse must be lowered to that of the spin lock.

In the PFG/TOCSY of sertindole (Figure 8) several extra cross peaks are seen compared with the COSY spectrum in Figure 2.

4.3 The Nuclear Overhauser Enhancement Spectroscopy Experiment

The NOESY\(^{[7]}\) experiment (Figure 9) correlates protons which are close in space through dipolar coupling. Whereas NOESY is an experiment of major importance in determining the structure of large molecules by distance constraints, the situation is less clear cut for small molecules. This is because the cross-peak sign and intensity are related to the tumbling rate of the molecules in solution and therefore to MW. Generally,
TWO-DIMENSIONAL NUCLEAR MAGNETIC RESONANCE OF SMALL MOLECULES

Figure 8 The TOCSY spectrum of 30 mM (10 mg) sertindole in chloroform-$d$ at 500 MHz with 128 increment of 1024 points and one scan per increment. The delay $d_1$ was 1 s and the spin-lock time including two trim pulses of 2.5 ms was 75 ms.

Figure 9 The pulse sequence for NOESY. The phase cycle is: $p_1$: $x$; $p_2$: $(x)_y$; $p_3$: $x$, $x$; $(x)$; $y$, $y$, $y$. $p_1$ was incremented for TPPI. The minimum number of scans is eight. The first pulse is incremented for TPPI.

small molecules are in the positive nuclear Overhauser enhancement (NOE) regime, but depending on the molecule, the solvent and the field strength, the NOE effect may be close to zero. It is therefore often preferable to perform 1-D NOE experiments instead, either as an alternative or as a test for the chance of success in the 2-D case. The NOESY should always be performed in the phase-sensitive mode in order to distinguish the NOESY peaks from residual antiphase COSY peaks. The COSY peaks may be reduced by random variation of the delay $d_2$. The sign of NOESY cross peaks will be opposite of that of the diagonal (for small molecules). An important parameter is the mixing time ($d_2$). For small molecules it should be set to the approximate longitudinal relaxation time $T_1$ or lower.

Exchange phenomena between loosely bound protons or slowly exchanging rotamers may give intense cross peaks that are in phase with the diagonal and the NOESY experiment is therefore valuable in the study of such phenomena. In this case the experiment is sometimes called EXSY (exchange spectroscopy). In Figure 10 is shown part of the 2-D NOESY spectrum of the potential drug Lu 28–179 (CAS 147817-50-3) as the hydrochloric acid salt. Small broad peaks in the reference spectrum, which may be mistaken for impurities, turn out to be a minor rotamer of the compound by showing strong exchange peaks with opposite sign to those from dipolar couplings. In the full spectrum exchange peaks between the water

Figure 10 Aliphatic part of the 500-MHz NOESY spectrum of Lu 28–179 (40 mM in dimethyl-$d_6$ sulfoxide). The filled lines are NOE cross peaks and the dotted lines are exchange peaks and diagonal. 256 Increments of 1024 points and 16 scans were acquired. Delay $d_1$ was 2 s and the mixing time ($d_2$) was randomly varied about 0.6 s. The total experiment time was 5 h 40 min.
signal and the hydrogen chloride proton can also be seen.

4.4 The Rotating Frame Overhauser Enhancement Spectroscopy Experiment

In cases where the NOESY experiment fails, because the molecular tumbling rate gives rise to approximately zero NOEs, the ROESY (rotating frame Overhauser enhancement spectroscopy) experiment\(^{(20)}\) may be an attractive alternative, since all sizes of molecules will behave as falling in the positive NOE regime. ROESY is another spin-lock experiment like TOCSY (section 4.2), and basically the pulse sequence is the same as in Figure 7, but the power of the spin-lock field is lower, and is usually generated by two continuous-wave decoupling pulses with opposite phases. A good choice of spin-lock time in ROESY is 250 ms.

Because of the resemblance with the TOCSY experiment, artifacts arising from TOCSY peaks may be expected. These will have opposite phase to the ROESY peaks.

4.5 Incredible Natural Abundance Double Quantum Transfer Experiment

The 2-D INADEQUATE (Incredible Natural Abundance Double Quantum Transfer Experiment)\(^{(21)}\) is at the borderline between homonuclear and heteronuclear experiments: it correlates nuclei of the same kind (\(^{13}\)C), but \(^{1}\)H decoupling is crucial. It is certainly not a routine experiment, but is mentioned here because of the interest that has been shown in the literature in attempts to improve it. The experiment gives the ultimate structural information on organic molecules, since the whole carbon skeleton can be traced out. On the other hand, the sensitivity is extremely low. This is because the natural abundance of the NMR-active \(^{13}\)C is only 1%. The likelihood that two \(^{13}\)C atoms are neighbors in a molecule is therefore only 1 : 10,000, and the available signal is divided into doublets due to \(J_{CC}\) splitting in the original sequences. Furthermore, it must be considered that the gyromagnetic ratio of the \(^{13}\)C nuclei is only 1/64 of that of the \(^{1}\)H nuclei. The basic pulse sequence is shown in Figure 11(a) together with one of the latest improvements\(^{(22)}\) in Figure 11(b). The 2-D INADEQUATE spectrum of menthol (CAS 1490-04-06) obtained with the pulse sequence in Figure 11(b) is shown in Figure 12. The correlation signals between the individual carbon atoms lie symmetrically about the diagonal on a horizontal line. Where the original sequence gives double quantum doublets, the newer sequence collects all signals in a single peak and therefore improves the S/N. A sample will give a reasonable 2-D INADEQUATE spectrum only if a 1-D single scan \(^{13}\)C spectrum obtained with a 90° pulse has an S/N of at least 25 : 1. The delay \(d_2\) must be adjusted to 1/4 \(J_{CC}\), where \(J_{CC}\) is the \(^{13}\)C–\(^{13}\)C one-bond coupling constant. Here a compromise must be made if a wide range of coupling constants is involved.

\[ \text{Figure 11} \quad \text{(a) Conventional 2-D INADEQUATE sequence. Delay } d_2 \text{ is } 1/4J_{CC}. \text{ The first two pulses are varied in } 45° \text{ steps. 6 HETERONUCLEAR CORRELATION EXPERIMENTS

6.1 Heteronuclear Correlation with $^{13}$C Detection

Direct $^{13}$C detection was the original way of performing $^{13}$C/$^1$H correlation experiments. These experiments may be performed on all NMR instruments capable of doing 2-D NMR and creating pulses with the $^1$H-decoupler channel. Since the experiments rely on the acquisition of a series of $^{13}$C spectra in the $F_2$ dimension, the sensitivity is limited. However, on instruments where the more sensitive indirect detection method requires rewiring of the spectrometer, direct detection can still be the method of choice for routine applications. The spectra of the two experiments mentioned are in magnitude mode.

One-bond correlation is obtained with the HETCOR experiment, for which the pulse program is given in Figure 15. As an example, the HETCOR spectrum of sertindole is shown in Figure 16. The delays $d_2$ and $d_3$ are set to $1/2J_{CH}$ and $1/3J_{CH}$, respectively.

In order to obtain two- or three-bond $^{13}$C/$^1$H correlation, the delays $d_2$ and $d_3$ can be adjusted to correspond to the long-range coupling constant, but in this case the sensitivity is low owing to relaxation during the lengthy sequence. The method of choice is instead the COLOC (correlation through long-range couplings) experiment. From the pulse sequence in Figure 17 it can be seen that the duration is constant with increasing $t_1$ values because $p_2$ and $p_4$ are moved within the sequence with increasing $t_1$. The evolution of long-range couplings takes place during $d_3$. Still, the sensitivity is considerably lower than for the one-bond experiment, as can be seen from the COLOC spectrum of sertindole in Figure 18.

6.2 Heteronuclear Experiments with $^1$H Detection

Indirect or inverse detection has had a major impact on 2-D NMR, especially in biomolecular applications, where the sensitivity of the direct methods is much too low. The gain in sensitivity in indirect detection, which
NUCLEAR MAGNETIC RESONANCE AND ELECTRON SPIN RESONANCE SPECTROSCOPY

Figure 14 JRES spectrum of 30 mM sertindole in chloroform-d at 500 MHz with 64 increments of 1024 points and four scans per increment. Delay $d_1$ was 1.5 s and the sweep width in $F_1$ was 100 Hz. Total experiment time was 10 min.

Figure 15 Pulse sequence for HETCOR. Delay $d_2$ must be adjusted to $1/2J_{CH}$ and $d_3$ to $1/3J_{CH}$. The phase cycle is: $p_1$: (x)$_s$, (−x)$_s$; $p_2$: (x)$_h$, (y)$_h$, (−x)$_h$, (−y)$_h$; $p_3$: x; $p_4$: x, y, x, y; acq.: (x,−x,y,−y)$_2$, (y,−y,−x,x)$_2$, (−x,x,−y,y)$_2$, (−y,y,x,−x)$_2$. Minimum number of scans is four.

is a factor of 16$^{(25)}$ comes from the difference in sensitivity for $^1$H and $^{13}$C, where the higher gyromagnetic ratio for $^1$H makes this the nucleus of choice for detection. If an X-nucleus decoupler is available, composite pulse decoupling, e.g. GARP (globally optimized alternating phase rectangular pulse)$^{(26)}$ can be done on carbon during acquisition. The most popular experiments for one-bond correlation are variants of HMQC (heteronuclear multiple quantum coherence)$^{(25)}$ and HSQC (heteronuclear single quantum coherence)$^{(27,28)}$. In general, HSQC has the advantage that $^1$H−$^1$H couplings do not evolve in $F_1$, thus giving better resolved spectra. The HSQC pulse sequence is given in Figure 19 and a phase-sensitive PFG version is shown in Figure 20. The delay $d_2$ is adjusted to $1/4J_{CH}$. In order to acquire this experiment in the phase-sensitive mode, the so-called echo/antiecho method must be used instead of TPPI. If the processing software does not have the needed
obtaining a magnitude spectrum. Figure 21 shows the processing feature, the experiment may be used for obtaining a magnitude spectrum. Figure 21 shows the 2-D spectrum of sertindole acquired with the sequence in Figure 20.

Figure 16 HETCOR spectrum of 0.15 M sertindole in chloroform-\textit{d} on a 250-MHz instrument with 256 increments of 2048 points and 16 scans per increment. Delay $d_1$ was 1 s, $d_2$ was 3.4 ms and $d_3$ was 2.3 ms. Total experiment time was 1 h 24 min.

Figure 17 The COLOC sequence. Delay $d_3$ must be larger than the product of the time increment and number of increments. Delay $d_1$ is defined as in Figure 15, but for long-range couplings. The arrow indicates that the two 180° pulses are moved forward with increasing $t_4$, while the whole sequence time remains constant. The phase cycle is: $p_1$ and $p_2$: $x,y,-x,-y$, $y,-x,-y,x$, $-x,-y,x,y$, $y,-x,y,x$, $-x,y,x,y$, $y,-x,y,x$, $-x,y,x,y$; $p_3$: ($x$)$_{16}$, ($y$)$_{16}$, ($-x$)$_{16}$, ($-y$)$_{16}$; $p_4$: $x,y,x,y$, $x,y,x,y$, $-x,y,-x,y$, $-x,-y,x,y$; $p_5$: $x,y,x,y$, $x,y,x,y$, $-x,y,-x,y$, $-x,-y,x,y$; $p_6$: $x,y,x,y$, $x,y,x,y$, $-x,y,-x,y$, $-x,-y,x,y$; acq.: $x,x,-x,-x,y,y,-y$. Minimum number of scans is 16.

Figure 18 COLOC spectrum of 0.15 M sertindole in chloroform-\textit{d} on a 250-MHz instrument with 256 increments of 2048 points and 256 scans per increment. Delay $d_1$ was 1 s, $d_2$ was 80 ms and $d_3$ was 40 ms. Total experiment time was 12 h.

Figure 19 Pulse sequence for phase-sensitive HSQC. The delay $d_3$ is 1/4 of $t_1$. The phase cycle is: $p_1$, $p_2$, and $p_4$: $x$; $p_3$ and $p_5$: $y$; $p_6$: $x,x,-x,-x$; $p_7$ and $p_{10}$: ($x$)$_{16}$, ($-x$)$_{16}$; $p_8$: $x,-x,x$, $p_9$: ($x$)$_{16}$, ($-x$)$_{16}$; $p_{11}$: $x,x,-x,x$; $p_{12}$: $x,-x,x,x$. The phase of $p_8$ is incremented for TPPI. Minimum number of scans is four.

For long-range $^1$H-\textsuperscript{13}C correlation, the experiment of choice is HMBC (heteronuclear multiple bond correlation),\textsuperscript{(29)} which also exists in a PFG version. The pulse sequence with optional PFGs is shown in Figure 22 and the HMBC spectrum of sertindole is shown in Figure 23. Note that many more correlation peaks are seen here than in the spectrum in Figure 18 obtained with the COLOC sequence. Since one-bond

Figure 20 Pulse sequence for phase-sensitive PFG/HSQC. Delay $d_2$ is $1/4J_{CH}$, $d_4$ is $1/8J_{CH}$, $d_3$ is the effective gradient length, and $p_3$ is a high power trim pulse. The phase cycle is: $p_1$, $p_2$, $p_3$, $p_6$, $p_7$, $p_8$, $p_{10}$, $p_{11}$, $p_{12}$, $p_{14}$, and $p_{15}$; $X$, $p_4$ and $p_8$; $Y$, $p_6$, $p_{14}$ and $p_{17}$; $X$, $-X$, $-X$; $p_{13}$; $X$, $-X$, $p_{17}$; $Y$, $Y$, $-Y$, $-Y$; acq.: $X$, $-X$, $-X$, $X$. The gradient ratio is 80:20, and the sign of $g_2$ is alternated for echo/antiecho detection.

Figure 21 PFG/HSQC spectrum of 30 mM (10 mg) sertindole in chloroform-$d$ at 500 MHz with 128 increments of 1024 points and two scans per increment. Delay $d_1$ was 1 s, $d_2$ was 1.9 ms, $d_3$ was 2.1 ms, $d_4$ was 1 ms and the high-power trim pulse was 2 ms. Total experiment time was 6 min.

couplings also evolve to some extent in the HMBC experiment, it is advantageous to avoid carbon decoupling. In this way, single and multiple bonds can easily be distinguished.

7 PSEUDO-THREE-DIMENSIONAL EXPERIMENTS

The term pseudo-three-dimensional (3-D) covers a range of pulse sequences developed for 3-D work which have been modified. The main feature of 3-D experiments is the combination of two 2-D experiments in which the two evolution periods are incremented independently. If one of the evolution periods is omitted, a 2-D spectrum will be the result. An example is phase-sensitive 2-D HMQC/TOCSY(30) shown in Figure 24, which may easily be performed. The main advantage of this experiment is
Figure 23 The PFG/HMBC spectrum of 30 mM sertindole in chloroform-$d$ at 500 MHz with 128 increments of 1024 points and two scans per increment. Delay $d_1$ was 0.9 s and $d_2$ was 0.05 s. Total experiment time was 6 min.

Figure 24 The pulse sequence for HMQC/TOCSY. Delay $d_2$ is $(1/2J_{\text{CH}})$ and the spin lock is adjusted for the wanted correlation type. For TPPI $p_3$ is incremented. Minimum number of scans is four.

that $^1\text{H}--^1\text{H}$ correlation in very crowded spectral areas may be spread out in the $^{13}\text{C}$ dimension, so that all cross peaks in a given row with one $^{13}\text{C}$ atom correspond to protons in a coupling network. The spectrum in Figure 25 was acquired without carbon decoupling. An important feature of this experiment type, when acquired without carbon decoupling, is that a $^1\text{H}--^1\text{H}$ correlation between protons with identical chemical shifts may be observed. For example, in Figure 25, a TOCSY correlation between symmetrically positioned protons in the piperidine ring of sertindole may be observed.

Figure 25 The phase-sensitive HMQC/TOCSY of 30 mM sertindole in chloroform-$d$ at 500 MHz with 128 increments of 1024 points and eight scans per increment. Delay $d_1$ was 1 s, $d_2$ was 3.7 ms and the spin-lock time including two 2.5-ms trim pulses was 70 ms. Total experiment time was 23 min.
Other variants including gradient versions combine an indirect $^1\text{H} - ^{13}\text{C}$ one-bond correlation with NOESY, $^{31}\text{C}$ COSY, and ROESY.

8 TWO-DIMENSIONAL NUCLEAR MAGNETIC RESONANCE ON SPIN-$\frac{1}{2}$ NUCLEI OTHER THAN $^1\text{H}$ AND $^{13}\text{C}$

In principle, all 2-D NMR experiments may involve any spin-$\frac{1}{2}$ nucleus if the abundance in the sample is sufficient and a probe head tunable for that nucleus is available. For small organic molecules, the most important are $^{15}\text{N}$, $^{19}\text{F}$, $^{29}\text{Si}$ and $^{31}\text{P}$. From sensitivity considerations, both homonuclear and HETCOR are possible with $^{19}\text{F}$, $^{29}\text{Si}$ and $^{31}\text{P}$, whereas the low natural abundance and low gyromagnetic ratio of $^{15}\text{N}$ allow only for indirect-detected HETCOR. An example of this is the $^1\text{H} - ^{15}\text{N}$ HMBC spectrum of sertindole in Figure 26. The spectrum was acquired with the pulse sequence in Figure 22, with a gradient ratio of 70:30:50.

Since the Larmor frequency of $^{19}\text{F}$ is close to that of $^1\text{H}$, the $^1\text{H}$ coil can in many cases be tuned and matched for $^{19}\text{F}$ with a reasonable result. This is how the spectra in Figures 27 and 28 of iodopentafluorobenzene were obtained. The $^{19}\text{F} - ^{19}\text{F}$ COSY spectrum in Figure 27 was acquired with the pulse sequence in Figure 4 and the $^{19}\text{F} - ^{13}\text{C}$ HMBC spectrum was acquired with the sequence in Figure 22, both without PFGs.

9 TWO-DIMENSIONAL NUCLEAR MAGNETIC RESONANCE ON RESIN-BOUND COMPOUNDS

The new era of combinatorial chemistry based on solid-phase synthesis has offered a new challenge to analytical methods, including NMR spectroscopy. Obtaining proton observed spectra of a compound bound to a resin swollen in an appropriate deuterated solvent requires magic angle spinning (MAS) in order to obtain a reasonable line width and resolution. NMR instrument vendors have introduced special probe heads with a deuterium lock channel suitable for this purpose, of which the most sophisticated have two channels and are equipped with a one-axis gradient coil. In principle, all the experiments
Figure 28 The $^{19}$F–$^{13}$C HMBC spectrum of 0.7 M iodopentafluorobenzene in chloroform-$d$ obtained without PFGs with the sequence in Figure 22 on a 250-MHz system. 64 Increments with 1024 points and 32 scans per increment. Delay $d_1$ was 2 s, $d_2$ was 25 ms. Total experiment time was 18 min.

described in the earlier sections may be conducted on resin-bound molecules, but there are some limitations. Some line broadening will occur even with fast spinning, and this is related to transverse relaxation processes, which are dependent on the mobility of the attached molecules in the swollen phase.

Thus, samples giving broad lines in the 1-D proton spectrum will give relatively poor S/N in the 2-D spectra if the pulse sequence is lengthy or if many $t_1$ increments are acquired. On the other hand, the time consumed by the 2-D pulse sequence will serve as an efficient filter for signals from the polymer backbone, which will have the lowest mobility.

Since the resolution observed in the 1-D proton spectra of this kind of sample is often so low that coupling patterns cannot be identified, the structural information that is available from 2-D spectra is of major importance. The use of the $F_2$ projection of the JRES experiment$^{(34)}$ and an E.COSY variant$^{(35)}$ has been described for revealing coupling constants in the $F_1$ dimension for samples with broadened signals. If, however, the size of the coupling constants is of less importance, more standard-like experiments may be used for obtaining structural information. Even though the effective sample volume may be as low as 25 µL, a resin-bound sample with a loading of 0.3 mmol g$^{-1}$ giving broad lines in the 1-D spectrum may give gradient-selected COSY, HSQC and HMBC spectra in total acquisition times of less than 6 min.$^{(36)}$

The Zeeman interaction is the physical phenomenon underlying the coupling of magnetic moments to magnetic fields. Its effects are detected in the features of spectra of samples taken while the sample is immersed in a magnetic field. Specifically, the features of nuclear magnetic resonance (NMR) spectra depend strongly on the coupling of nuclear spins to various sources of magnetic field.

1 INTRODUCTION

Magnetic resonance is a staple of analysis in the modern chemistry laboratory, particularly for the analysis of organic materials. More generally, it is applied to a range of chemical and physical systems, both organic and inorganic, having nuclei with magnetic moments. It has become a major tool in medical diagnoses through the development of imaging techniques that provide three-dimensional pictures of tissues. The application to the study of a wide variety of materials is a testament to the versatility and continued development of NMR techniques.

These NMR techniques rely on the singular physical fact that, in a magnetic field, the intrinsic nuclear angular-momentum (spin) states lie at different energies because of the presence of the magnetic field – the Zeeman interaction – first discovered by Pieter Zeeman in a different situation and explained by Lorentz (see Condon and Shortley). The concept is widely applied to understand interactions with magnetic fields, one of which is the NMR experiment.

2 NUCLEAR SPINS

Nuclei are small islands carrying specific amounts of positive charge and mass, as exemplified in Table 1. They are quantum objects. In NMR studies, one generally focuses on the properties of the nucleus in its ground state, as addressed through measurement of the magnetic properties related to the intrinsic angular momentum.

Angular momentum, as a classical property, is a vector describing circularity of motion. Consider a single particle of mass, \( m \), in motion about a point. Its position relative to the point being \( r \) and its linear momentum being \( p \), the instantaneous orbital angular momentum, \( \mathbf{l} \), is given by the simple formula given in Equation (1):

\[
\mathbf{l} = \mathbf{r} \times \mathbf{p} = m \mathbf{r} \times \mathbf{v}
\]

where the second equality indicates that angular momentum depends on mass and instantaneous velocity, \( v \). For a system of many particles, the total angular momentum is a vector sum of contributions from all particles. In many situations, one focuses on motion about some axis passing through the center of mass of the system.

The manner in which angular momentum changes with time is determined by the torque, \( \tau \), to which the system is subject, and is given by the formula in Equation (2):

\[
\frac{d\mathbf{l}}{dt} = \mathbf{\tau}
\]

For a system subject to no torque, the angular momentum is time independent, with its magnitude and orientation fixed. The description of a vector such as the angular momentum requires one to specify the projections of the vector along the three axes of a Cartesian coordinate system, such as shown in Figure 1, or the equivalent.

One often thinks of angular momentum in terms of the motion of a particle tethered in some way, such as an electron in an orbit. However, there are many systems with angular momentum whose equations of motion are of the same form as those of the tethered particle. In
magnetic resonance, we focus particularly on the intrinsic angular momentum of nuclei and electrons.\(^4\)

The particles are so small that one must consider them as quantum objects, for which one seeks the possible stationary states of a system, the equivalent of determining the time-independent properties in a classical system. For a system of particles in motion, there are states having constant magnitude of the angular momentum.

Unlike classical systems, not all variables of a quantum system may be simultaneously known with infinite precision. In particular, one is allowed by the uncertainty principle to measure only the magnitude and one component of the angular momentum precisely, with the result that there exists some uncertainty about the angular placement of the angular momentum vector. For a nucleus, the square of the magnitude of the intrinsic angular momentum, \(I\), is a fundamental property of the state of the nucleus, determined by the spin quantum number, \(I\).\(^5\) Its value is \(I(I + 1)h^2\), where \(h\) is a fundamental constant (Planck’s constant divided by \(2\pi\)) equal to \(1.0545726 \times 10^{-34}\) Js. \(I\) will always be a non-negative half or whole integer, as indicated in Table 1 for representative nuclear isotopes. In the quantum mechanical description of this kind of system, the state is also characterized by the projection along any one of the axes, usually chosen to be the \(z\)-axis of the coordinate system in which the system is described.\(^5\) The value of the projection of the angular momentum along this axis is restricted to certain values \(M\), where \(-I \leq M \leq +I\). In isotropic space, these states of different \(M\) have the same energy. There are \(2I + 1\) different states at this ground nuclear energy level.

### 3 MAGNETIC MOMENTS

A charge of magnitude, \(Q\), moving with velocity, \(v\), experiences a force, \(F_{\text{magnetic}}\), when interacting with a field of magnetic induction, \(B\), whose source is other remote moving charges (Equation 3):\(^4\)

\[
F_{\text{magnetic}} = Qv \times B
\]  

This force causes the charge to circulate about the direction of the magnetic induction. The torque on such a system describes this change of direction of the flow of charge (Equation 4):

\[
\tau = Qr \times v \times B
\]

For a system of charges \(Q_i\), the total force is given by a sum over the distribution of charges (Equation 5):

\[
F_{\text{magnetic}} = \sum_i Q_i(r_i) v_i(r_i) \times B(r_i)
\]
Analogously, the torque about the origin is given by Equation (6):

\[ \tau = \sum_i \frac{Q_i}{m_i} r_i \times v_i(r_i) \times B(r_i) \]  

(6)

One may write analogous equations for a continuous distribution of charge.

If the magnetic induction is uniform across a distribution of constant total charge such as a nucleus, there is no net magnetic force. However, the magnetic torque on such a distribution is not zero. For example, for a distribution of discrete charges, it is (Equation 7):

\[ \tau = \sum_i \frac{Q_i}{m_i} r_i \times p_i \times B \]  

(7)

One defines the magnetic moment of the distribution, \( m \), by the term in brackets. The magnetic moment is a function only of the variables of the distribution. The classical equation of motion of a magnetic moment in a magnetic field of induction \( B \) is then (Equation 8):

\[ \frac{dl}{dt} = \tau = m \times B \]  

(8)

The magnetic moment and the total angular momentum are proportional:

\[ m = \gamma l \]  

(9)

where \( \gamma \) is the magnetogyric (also called the gyromagnetic) ratio of the system, which gives the classical equation of motion of the magnetic moment in a field of induction \( B \) (Equation 10):

\[ \frac{dm}{dt} = \gamma m \times B \]  

(10)

The existence of a torque on the magnetic moment in a magnetic field is an indication that the potential energy of the system depends on the relative orientation of the angular momentum vector and the magnetic field. One may show that the energy contribution from this effect is of the form (Equation 11):\(^{(4)}\)

\[ E_{\text{magnetic}} = -m \cdot B \]  

(11)

This is the Zeeman energy of a magnetic moment in a magnetic field. In a quantum mechanical system, the states of constant energy are the states of constant angular momentum projection along the direction of the magnetic induction. While these equations are derived classically for a small current loop,\(^{(2)}\) similar equations apply for the Hamiltonian operators of quantum systems such as nuclear magnets.

4 THE ZEEMAN INTERACTION, HISTORICALLY

Although the Zeeman interaction is a commonly used concept in NMR, its first observation and explanation were the result of observing atomic spectra in the presence of a magnetic field. Certain spectral lines that are single in the absence of a field appear as narrowly spaced multiplets when spectroscopy is carried out in the presence of a magnetic field. The presence of an energy term as given in Equation (11) explains these results quantitatively.

Consider one of the transitions of the sodium atom (Figure 2). The \( ^2S_{1/2} \rightarrow ^2P_{1/2} \) transition is well known to occur at a transition energy of 16961 cm\(^{-1}\).\(^{(6)}\) (This is one component of the famous sodium D line). For a system of atoms in a magnetic field irradiated with unpolarized light, one detects four transitions in the region of this nominal energy, where only one is detected outside the magnetic field. The spacing of these lines is proportional to magnetic field strength. One may understand this effect by the presence of additional energies. Each of the two terms, \( ^2S_{1/2} \) and \( ^2P_{1/2} \), has a total angular momentum of \( 1/2 \). Each, according to quantum mechanics, consists of two states, corresponding to different values of \( M_J \), the quantum number for the angular momentum component along the field. These states differ in energy in the presence of the magnetic field, whereas they are of the same energy in the absence of the field. In the case of one substate, the Zeeman interaction slightly raises the energy relative to the nominal energy, and the other energy is slightly lowered. The result is that transitions between states occur at slightly different energies owing to the Zeeman interaction.

![Figure 2](image-url)
5 THE ENERGIES OF NUCLEAR SPINS IN A MAGNETIC FIELD

Nuclei are charged particles described by the intrinsic angular momentum (spin). In a magnetic field, the states of different angular momentum projection along the field have energies that depend on the projection quantum number, the induction strength and the magnetogyric ratio, according to Equation (12):

$$E_M = -M\gamma \hbar B$$  \hspace{1cm} (12)

As a result of the Zeeman interaction’s dependence on the quantum number $M$, there is a series of energy levels ($2I + 1$ levels for a nucleus of spin quantum number, $I$), each of slightly different energy in the presence of a magnetic field. The spacing between them depends linearly on the magnetic induction, as shown in Figure 3 for spin 1/2. For a spin 1, there will be three states, and for a spin 3/2 there will be four states, etc.

Transitions between the levels by energy absorption from an electromagnetic field cause the nuclei to change between these states, as indicated by the bold arrow in Figure 3. In the typical experiment these are single-quantum transitions, $\Delta M = \pm 1$. The energy difference between the two states determines the type of electromagnetic field to produce the transitions, as given in Equation (13):

$$\Delta E = \hbar \gamma B = \hbar \omega_L$$  \hspace{1cm} (13)

The energy difference depends on the magnetic field, and also on the size of the magnetogyric ratio. The product of the magnetogyric ratio and the magnetic field is an angular frequency, $\omega_L$, the Larmor frequency. For typical magnitudes of magnetic fields achievable in the laboratory, the energy differences are quite small, and nuclear Larmor frequencies are in the radiofrequency region of the electromagnetic spectrum. Thus, NMR spectroscopy is thought of as a radiofrequency experiment, although it may occur at other frequencies depending on the magnetic field strength. Because the energy spacing is so small, the population difference between the two states is quite small and the signals are quite weak compared with many other forms of spectroscopy.

From the sizes of the magnetogyric ratios in Table 1, it can be seen that the resonance of each nucleus occurs at a characteristic frequency quite different from those of other nuclei in a field of magnetic induction $B$, so that one may interrogate only one (or at most a limited number of different) nuclear species in an experiment. For example, in a field in which the proton resonance frequency is about 100 MHz, that of $^{13}$C occurs near 25 MHz.

6 VECTOR AND TENSOR DESCRIPTIONS IN NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

Magnetic fields are vectors, as are the magnetic moments of nuclei. The description of the energies of coupling between fields and moments, among moments and with other physical fields are couched as quantities proportional to products of the components of these vectors. The most general way to express these relationships is through tensors that specify the dependence of energies on the various components of vectors (see, for example, Jeffreys[7]). For example, the energy of the direct coupling of a magnetic moment to a magnetic field through the Zeeman interaction Equation (11) was stated to be proportional to the dot product of the vectors. One may think of this product as having the form (Equation 14):

$$E_{\text{magnetic}} = -\mathbf{m} \cdot \mathbf{B}$$  \hspace{1cm} (14)

where the interposed matrix describes how the coupling of each component of $\mathbf{m}$ to each component of $\mathbf{B}$ contributes to the energy. In this case, only components of the two vectors along the same coordinate axis couple to produce energy, as indicated by zeros in the elements that would indicate coupling between components along different axes.

For more general cases, the energy of interaction may depend on the products of components along different axes. Thus, bilinear interaction energies (or, in quantum systems, the Hamiltonian operators bilinear in the operators of the system) may be written in the more
general form (Equation 15):

\[
E_{\text{interaction}} = X \cdot \begin{pmatrix} t_{11} & t_{12} & t_{13} \\ t_{21} & t_{22} & t_{23} \\ t_{31} & t_{32} & t_{33} \end{pmatrix} \cdot Y
\]

\[
= X \cdot T \cdot Y
\] (15)

where \( T \) is a matrix of coefficients that describes the coupling between components of the vectors \( X \) and \( Y \).

An important feature of tensor interactions is the relation of the form of the information in one reference frame to that in another. For example, interactions are naturally expressed in terms of molecular coordinates defined by the features of the molecule and its surroundings, whereas the experiment is defined by a coordinate system specified by the magnetic field and the direction of a coil that emits and detects radiofrequency radiation. The relation of these two descriptions of the same interaction is determined by the relation of the expression of the tensor in the first frame to that in the latter.

The use of symmetry can often simplify the task of relating tensor descriptions from one frame to another. A general second-rank Cartesian tensor can be expressed as the sum of three tensors, each of which has certain symmetry properties (Equation 16):

\[
T = T_0 + T_1 + T_2
\] (16)

The elements of the matrix of \( T_0 \) have the following property (Equation 17):

\[
t_{0,ij} = T_0 \delta_{ij}
\] (17)

\( T_0 \) is related to the trace of the tensor, given in terms of the diagonal elements of the tensor \( T \) (Equation 18):

\[
T_0 = \frac{1}{3} \sum_i t_{ii}
\] (18)

The tensor \( T_1 \) is antisymmetric about the diagonal (Equation 19):

\[
t_{1,ij} = -t_{1,ji}
\] (19)

The tensor \( T_2 \) is symmetric (Equation 20):

\[
t_{2,ij} = t_{2,ji}
\] (20)

and has a trace of zero (Equation 21):

\[
\sum_i t_{2,ii} = 0
\] (21)

The elements of these two tensors may be expressed in terms of the elements of the general tensor, \( T \) (Equations 22 and 23):

\[
t_{1,ij} = \frac{1}{2} (t_{ij} - t_{ji})
\] (22)

and

\[
t_{2,ij} = \frac{1}{2} (t_{ij} + t_{ji}) - T_0 \delta_{ij}
\] (23)

An examination of Equation (15) indicates that the right-hand side may be considered the dot product of two vectors. If one defines \( Z \) in the following manner (Equation 24):

\[
Z = T \cdot Y
\] (24)

the overall interaction is of the form of the dot product of two vectors. Specifically, if one vector is the magnetic moment, the resulting interaction is of the form of a Zeeman interaction if one considers the other vector to be an “effective magnetic induction.” In many cases, interactions spins experience can be put in this form. In some cases, the interaction is said to result from a “local” or “effective” field.

7 COUPLING OF SPINS MODELED AS ZEEMAN INTERACTIONS

Most spin interactions in NMR spectroscopy are represented by second-rank tensors of the type given above. In one convenient way, the interactions may be viewed as Zeeman-like couplings to “effective fields.” As examples, we quote these for the most common interactions.

7.1 Shielding

The interaction that makes NMR spectroscopy particularly useful for analysis of chemical structure is electronic shielding of the nucleus from the field. Generally, the effect is measured as the chemical shift of the resonance with respect to some reference species.

The origin of shielding is the coupling of the nuclear spin to the orbital angular momentum of the electrons in the vicinity of the nucleus.8,9 The simplest physical model is that of an unfettered charged particle, such as an electron, in a magnetic field circulating about the field direction. Such a circulating charge produces a field of its own, which contributes to the field at the site of a nucleus in the nearby region. The NMR experiment detects these variations in field as differences in effective nuclear Larmor frequencies at the various sites.

In quantum mechanical developments, the shielding is given as a second-order perturbation of the main Zeeman interaction by the direct interaction of the nuclear spin with the orbital angular momentum of the electrons in the molecular orbitals.7 The resulting energy shift of a particular nuclear spin state is given by integrals over
the electronic state. The shielding field does not have to be collinear with the polarizing field, \( B_0 \), and the energy corresponding to this interaction is of the form (Equation 25):

\[
E_{\text{shielding}} = m \cdot \sigma \cdot B_0 = m \cdot B_{cs}
\]

(25)

where \( \sigma \) is the shielding tensor, and \( B_{cs} \) is the chemical-shielding field. Expressions for the chemical shielding in terms of the molecular orbitals are given in texts on NMR. (see, for example, Slichter\(^{10} \)). The representation of the shielding tensor in some Cartesian coordinates \((x, y, z)\) can be divided into a sum of three tensors, as indicated above (Equations 26–29):

\[
\sigma = \sigma_0 + \sigma_1 + \sigma_2
\]

(26)

where

\[
\sigma_0 = \begin{pmatrix}
\sigma_{iso} & 0 & 0 \\
0 & \sigma_{iso} & 0 \\
0 & 0 & \sigma_{iso}
\end{pmatrix}
\]

(27)

and

\[
\sigma_1 = \frac{1}{2} \begin{pmatrix}
0 & (\sigma_{xy} - \sigma_{zx}) & (\sigma_{xz} - \sigma_{zy}) \\
(\sigma_{zx} - \sigma_{xy}) & 0 & (\sigma_{yz} - \sigma_{zy}) \\
(\sigma_{zy} - \sigma_{yz}) & (\sigma_{yz} - \sigma_{zy}) & 0
\end{pmatrix}
\]

(28)

and

\[
\sigma_2 = \frac{1}{2} \begin{pmatrix}
2(\sigma_{zx} - \sigma_{yy}) & (\sigma_{xy} + \sigma_{zx}) & (\sigma_{xz} + \sigma_{zx}) \\
(\sigma_{zy} + \sigma_{zx}) & 2(\sigma_{xy} - \sigma_{iso}) & (\sigma_{xz} + \sigma_{zx}) \\
(\sigma_{zy} + \sigma_{zx}) & (\sigma_{zy} + \sigma_{zx}) & 2(\sigma_{xx} - \sigma_{iso})
\end{pmatrix}
\]

(29)

Some physical qualities expressible as tensors have inherent symmetries requiring specific relationships among tensor elements. Although it is not required by the physics of NMR spectroscopy, the chemical-shielding tensor is often found to be symmetric.\(^{11} \) Thus, \( \sigma_1 \) is often practically taken to be the null matrix. Using this simplification (Equation 30),

\[
B_{cs} = \sigma_0 \cdot B_0 + \sigma_2 \cdot B_0
\]

(30)

The chemical shielding tensor in a particular molecular frame [the principal-axis system (PAS)] has the form (Equations 31 and 32):

\[
\sigma_{\text{PAS}}^0 = \sigma_{\text{iso}} \begin{pmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{pmatrix}
\]

(31)

and

\[
\sigma_{\text{PAS}} = \delta \begin{pmatrix}
-\frac{1}{2}(1 + \eta) & 0 & 0 \\
0 & \frac{1}{2}(1 - \eta) & 0 \\
0 & 0 & 1
\end{pmatrix}
\]

(32)

where the isotropic shielding, \( \sigma_{\text{iso}} \), the anisotropy \( \delta \), and the asymmetry \( \eta \) are given in terms of the principal components, \( \sigma_{XX} \), \( \sigma_{YY} \), and \( \sigma_{ZZ} \) in the PAS (Equations 33–35):

\[
\sigma_{\text{iso}} = \frac{1}{3}(\sigma_{XX} + \sigma_{YY} + \sigma_{ZZ})
\]

(33)

\[
\delta = \frac{1}{3}(\sigma_{XX} + \sigma_{YY}) - \frac{1}{3}(\sigma_{XX} + \sigma_{YY} + \sigma_{ZZ})
\]

(34)

\[
\eta = \frac{\sigma_{YY} - \sigma_{XX}}{\delta}
\]

(35)

In any other frame of reference obtained by rotation of the coordinate axes, the tensor is given by the following relation to the tensor in the PAS (Equation 36):

\[
\sigma = \mathbf{R} \cdot \sigma_{\text{PAS}}^0 \cdot \mathbf{R}^{-1} + \mathbf{R} \cdot \sigma_{\text{PAS}}^0 \cdot \mathbf{R}^{-1}
\]

(36)

where \( \mathbf{R} \) is a transformation matrix that connects the two reference frames.

The frame of interest in NMR spectroscopy is one in which one of the axes is along the direction of the magnetic induction, usually the \( z \)-axis since it is the component of the magnetic moment along this axis that, in the first approximation, determines the resonance condition. In high magnetic fields (which is usually satisfied by the fields achievable in modern magnets), only the \( zz \) component of the tensor in this frame is measurable with NMR. This component depends on the rotation angles that define \( \mathbf{R} \); these are the Euler angles, \( \alpha \), \( \beta \) and \( \gamma \), which describe the relation of the PAS frame to the magnetic field frame.\(^{16} \) In terms of these angles, one obtains an explicit form for this component of the shielding tensor (Equation 37):

\[
\sigma_{zz} = \sigma_{\text{iso}} + \delta \frac{3 \cos^2 \beta - 1}{2} + \frac{1}{2} \eta \sin^2 \beta \cos 2\gamma
\]

(37)

The total effective field at a particular nuclear site is given by the sum of the chemical-shielding field and the strong external polarizing field, \( B_0 \) (Equation 38):

\[
B = (1 - \sigma_{zz})B_0
\]

(38)

Frequently, one examines the NMR spectrum of a solution of molecules. The thermal motions of the molecules in the solution produce a modulation of the orientation of the PAS relative to the magnetic field frame. When this motion is fast and isotropic, the average field felt by the nuclei may be calculated as the average over all possible values of the Euler angles. In this case, the effective field becomes (Equation 39):

\[
B = (1 - \sigma_{\text{iso}})B_0
\]

(39)

an approximation used in the analysis of most NMR spectra of isotropic solutions.
For solid samples, the chemical shielding field depends on the orientation of the PAS to the magnetic field axes. For samples in which several orientations of the PAS relative to the field direction are simultaneously present, the NMR spectrum will not generally show a single sharp line for a particular nuclear site, as is seen in solution. Thus, for single-crystal samples, the NMR spectrum reflects the number of geometrically unique sites in a unit cell. If the sample is a powder, then there will exist a range of values of the chemical shielding for a single site, and the spectrum for a nucleus will be a band whose range and relative shape are determined by the principal values of the shielding tensor.\(^{(12)}\)

### 7.2 The Dipole–Dipole Interaction

Nuclear spins (or, for that matter, electronic spins) are sources of magnetic field that can affect the NMR properties of other nearby spins. This coupling of nearby spins occurs by the direct dipole–dipole interaction. For example, Figure 4 shows schematically the geometry of two magnetic moments that happen, in this case, to be polarized in the same direction. The moment, \(\mathbf{m}_1\), acts like a bar magnet, producing a magnetic field at the site of \(\mathbf{m}_2\), with which the latter interacts by a Zeeman interaction. The energy of this interaction is (Equation 40):

\[
E_{dd} = -\mathbf{m}_2 \cdot B_{dd,1}
\]  

(40)

The form of the field due to a dipole is found from the classical model of a steady-state current distribution.\(^{(2)}\) Such a distribution is described by its magnetic moment, \(\mathbf{m}\). At a point, \(\mathbf{R}\), remote from this distribution, the vector potential is given by Equation (41):

\[
A(\mathbf{R}) = \frac{\mathbf{m} \times \mathbf{R}}{|\mathbf{R}|^3}
\]  

(41)

From this form, one finds the magnetic induction, \(\mathbf{B}(\mathbf{R})\), as the curl of this vector potential. The resulting dipolar field of magnetic moment, \(\mathbf{m}_1\), is (Equation 42):

\[
B_{dd,1}(\mathbf{R}) = 3 \frac{(\mathbf{R}\mathbf{m}_1)}{|\mathbf{R}|^3} - \frac{1}{|\mathbf{R}|^3} \mathbf{m}_1
\]  

(42)

This dipolar field has components along the dipole, \(\mathbf{m}_1\), and along the vector, \(\mathbf{R}\), connecting the position of the dipole with the point at which the induction is measured. In many materials, the field at a point is determined by a number of magnetic moments located at a variety of points, \(\{\mathbf{R}_i\}\). In this case, the dipolar field is a sum over all such sources of magnetic induction (Equation 43):

\[
B_{dd}(\mathbf{R}) = \sum_i \left( \frac{3(\mathbf{R} - \mathbf{R}_i)\mathbf{m}_i}{|\mathbf{R} - \mathbf{R}_i|^5} (\mathbf{R} - \mathbf{R}_i) - \frac{1}{|\mathbf{R} - \mathbf{R}_i|^3} \mathbf{m}_i \right)
\]  

(43)

The interaction may also be couched in terms of a tensor product of the type (Equation 44):

\[
E_{dd} = \mathbf{m}_1 \cdot \mathbf{D} \cdot \mathbf{m}_2
\]  

(44)

where the tensor \(\mathbf{D}\) is the dipole–dipole tensor, whose elements may be determined from, for example, Equation (42).

Like the chemical-shielding tensor, the dipolar tensor may be expressed with respect to various reference frames, and the form of the interaction in one frame is related to that in another by a transformation described by a tensor \(^{(8)}\) that depends on the Euler angles. One may show that the isotropic part of the dipolar tensor is zero, a fact that has the profound effect that, for a molecule undergoing rapid isotropic tumbling, the time-averaged dipolar interaction does not affect the energy of the states in first order. In the NMR spectroscopy of molecules in nonviscous solutions, the dipolar coupling does not have to be considered in calculating observed shifts or splittings. (It does affect the NMR spectrum in second order and is often a major consideration in specifying line widths and relaxation times.) For solids, the dipolar coupling among the spins of a sample can be the major effect in an NMR spectrum, particularly for spin 1/2. Because of the large number of spins in a material, the spectrum must be interpreted in terms of a dipolar field of many spins, rather than that of a single spin. The development of techniques to overcome the effects of the dipolar field in a solid to reveal smaller interactions is a major triumph of the study of the physics of spin systems.\(^{(11)}\)

### 7.3 The J Coupling Between Spins

In addition to the direct coupling of nuclei via the dipolar coupling and the coupling to the orbital motion of the electrons that gives rise to the chemical shielding, nuclei also experience an electron-mediated coupling, known as the J coupling or the indirect coupling, that may also be treated as a Zeeman coupling.\(^{(13,14)}\) The origin of this effect is a slight interaction between a nuclear spin and
an electron that slightly modifies the state of the electron. This perturbation is then “felt” by the second nucleus with which the electron is in contact. The net effect is that the energy states of the spins depend on their relative spin states (Equation 45):\[ E_J = m_1 \cdot J \cdot m_2 \] (45)

The elements of the tensor $J$ are integrals of functions of the electronic coordinates over all participating molecular orbitals.\[ ] Once again, one sees that, by treating the product of the $J$ tensor with one of the magnetic moments as an effective magnetic field, this interaction is also of the form of a Zeeman interaction with a “local field.”

The indirect coupling’s tensor qualities can be seen, in some cases, in the spectra of solids.\[ ] However, in NMR spectra of isotropic solutions, one detects only the isotropic average indirect coupling between spins. Geometric effects are seen in the size of the isotropic coupling constants measured in solution because motion about bonds may be restricted. Thus, the values of three-bond couplings are determined by internal conformations through devices such as the Karplus relation.\[ ]

The $J$ coupling presupposes the existence of a difference between nuclei due to differences in chemical shielding. I have tried to describe the effects of the various interactions in a classical manner as due to effective fields from the various interactions. Such a description works well if the sizes of the interaction energies are quite different. However, when the magnitudes of interactions become comparable, then one must consider the quantum nature of the interferences between the two interactions beyond the simple effective-field approach. The results for the case one is most likely to encounter, the $J$ coupling and the chemical-shielding difference, have been worked out in most texts on NMR, and the effects are described in detail.\[ ]

8 CONCLUSIONS

The interaction of spins with magnetic fields produces splittings of energy levels, which are detected by energy absorption. One such coupling is the Zeeman interaction with an applied field of magnetic induction, $B$. Other interactions of spins may be viewed as Zeeman interactions with “effective” fields. Specifically, the coupling to the orbital angular momentum of the electrons leads to the shielding by an effective field related to the electronic state. The direct dipolar coupling of a magnetic moment with the field produced by other magnetic moments can also be considered to result from a Zeeman interaction. The $J$ coupling is represented by an effective electron-mediated field produced by interaction of electrons with a nucleus at another site. While the classical results of Zeeman-like models hold in many cases, where spins are strongly coupled quantum mechanical models of the interactions of several spins may not easily be pictured in terms of an effective field. Nevertheless, the concept of an effective Zeeman field often provides insight into the physics underlying the observation of multiple resonance lines in a spectrum.

Chemical Analysis by Nuclear Methods: Introduction

Zeev B. Alfassi
Ben Gurion University, Beer Sheva, Israel

Chemical analysis by nuclear methods is usually an elemental analysis, i.e. it determines the contents of the various elements in the analyzed sample but cannot tell in what chemical form (compounds, valence states) they are. The analysis is based on either a reaction of the analysed element with nuclear projectiles (neutrons or accelerated charged particles, e.g. electrons, protons, heavy ions or \( \gamma \)-photons) (see the following articles within this section: Instrumental Neutron Activation Analysis; Instrumental Neutron Activation Analysis: Gamma Lines Table; Charged Particle Activation Analysis; Cyclic Activation Analysis; Particle-induced \( \gamma \)-Ray Emission; PIXE (Particle-induced X-ray Emission); Radiochemical Neutron Activation Analysis; Nuclear Reaction Analysis and Scattering and Absorption of \( \gamma \)-Rays and Thermalization and Disappearance of Neutrons) or on the scattering of accelerated charged particles. The reaction can be written in the same form as a chemical reaction:

\[
\text{Target + Projectile} \xrightarrow{} \text{Light product} + \text{Heavy product}
\]
or in the more concise form of writings of nuclear physics:

\[
\text{Target (Projectile, Light product)} \xrightarrow{} \text{Heavy product}
\]

Thus, for example, the first production of artificial radionuclide by Joliot and Curie was done by the reaction of \( \alpha \)-particles with aluminum metal:

\[
^{27}\text{Al} + \alpha \xrightarrow{} ^{30}\text{P} + n \quad (\alpha \text{ is the } ^{4}\text{He nucleus})
\]
or in the physics notation:

\[
^{27}\text{Al}(\alpha, n) ^{30}\text{P}.
\]

The light product is similar to the projectile and can be a neutron, a small charged particle or a photon. The basis of the nuclear methods for chemical analysis via nuclear reaction (nuclear activation) is the measurement of the amount of light or heavy product formed in a known flux of projectiles for a known length of time (irradiation time). The amount produced is proportional to the number of target atoms, and hence measurement of the amount of the products yields the amount of target atoms. The amount of products formed is too small to be measured chemically (except in very rare cases), and the only way to measure them is by the nuclear physics method of pulse counting. The light product can be measured due to its energy if it is a photon or a charged particle of high kinetic energy, or due to its reaction if it is a neutron.

The common denominator of all these processes is that they must be done a very short time after formation of the product, otherwise the light product will lose either its energy or its identity by reaction with the surrounding media. Consequently, measurement of the light product must be done during bombardment of the target with projectiles. This kind of measurement is called prompt activation analysis.

A similar situation exists when the analysis is done by scattering of the projectile, and the measurement is made simultaneously with the irradiation. In this case qualitative analysis is based not on the identity of the products but rather on the kinematics of the scattering, i.e. the energy and direction of the scattered particles. Quantitative measurement is done by counting the number of scattered particles. In the case where the heavy product is radioactive, i.e. it undergoes a spontaneous nuclear transformation, its identity and amount can be measured by its radioactivity. Because the radioactivity can be measured after the end of the interaction between the target and the beam of projectiles, this method of analysis is called delayed activation analysis. Because the heavy product must be radioactive, not all elements can be measured with each projectile. However, by careful choice of the bombarding projectile, almost every element can be determined.

Because many elements are activated simultaneously, the radioactivity measurement must yield both the identity of the radioactive nuclides and their amounts. The term that is sometimes used – radioisotopes – is wrong because when saying isotopes we should say of what element, see Elemental Analysis by Isotope Dilution. Nuclide is the nuclear physics term that is parallel to “atom” in chemistry. It consists of a nucleus (composed of neutrons and protons) and electrons around it. Because the identity of radionuclides (a short term for radioactive nuclides) in a mixture usually cannot be determined from \( \beta^- \) - or \( \beta^+ \)-emission (unless there are only very few in the mixture and they differ strongly in their half-lives or energy of the \( \beta \)-particles), only radionuclides that also emit \( \gamma \)-rays can be used in activation analysis. The radionuclides used for identification are called indicator radionuclides. Only few pure \( \beta^- \)-emitting indicator radionuclides, such as \( ^{32}\text{P} \), can be used in activation analysis. In this case the phosphorus should be separated from the other radionuclides in the activated sample or the other radionuclides are left to decay before the measurement. The chemical analysis by nuclear activation in which chemical separation precedes the radioactivity measurement is named Radiochemical Neutron Activation Analysis, whereas analysis by nuclear activation with direct measurement of the nuclear activity is named Instrumental, see Instrumental Neutron Activation Analysis and Instrumental Neutron Activation Analysis: Gamma
Lines Table. Owing to the method of measurement of pulse counting, very small amounts of radionuclides can be assessed quantitatively. This and the fact that most natural nuclides are nonradioactive are the basis for the use of radionuclides as tracers in chemical analysis.

Scattering of charged particles is measured both in the forward direction (by Elastic Recoil Detection Analysis) and in the backward direction (by Rutherford Backscattering Spectroscopy). In the first years of studies mainly the scattering of light ions was studied, but later the scattering of heavier ions became more frequent. The widespread availability of 2–3-MeV accelerators made their use more popular. However, in forward scattering they are restricted to the analyses of H and D. Heavier elements can be analyzed with the beams by backward scattering or by forward scattering of heavier ions. In the recent Ion Beam Analysis Conference at Lisbon (1997) there were two papers on He-induced elastic recoil detection analysis compared to 26 papers on heavy-ion elastic recoil detection analysis. However, for routine analysis the situation is different owing to the availability of the low-energy He accelerators.

Activation by neutrons is carried out mainly in the delayed mode, where very low detection limits can be obtained. Prompt activation is used mainly for in situ and on-line analysis and for elements that cannot be determined by the delayed mode due to the product being nonradioactive or having too short or too long a half-life. An example is the determination of hydrogen and nitrogen atoms by PGNAA (prompt gamma neutron activation analysis), mainly in food samples, see Prompt γ-Neutron Activation Analysis.

The slowing down of high-kinetic-energy charged particles passing through matter allows not only the determination of the total concentrations of some elements but also their distribution as a function of distance from the surface, i.e. depth profiles of the concentrations of the various elements. The slowing down can change the energy of the emitted charged particle, e.g. in the reaction $^{10}$B(n, α)$^7$Li. The energy of the α-particle crossing the surface of the sample to reach the detector indicates the distance the α-particle travels in the sample via the energy loss from the original energy of the α-particle.

The slowing down of an impinged high-energy projectile can reduce its energy to the range where a resonance reaction can occur. Thus, by changing the original energy of the projectile, the depth profile of the concentration can be measured.

All nuclear methods, except those using radiotracers, use either nuclear reactors or ion accelerators. These are quite expensive machines that are not found in common analytical laboratories but rather in special laboratories. Many of these methods involve the cooperation of chemists and nuclear physicists.
There is a trend in many analytical techniques towards the use of smaller sizes of the test portion, and sometimes submilligram amounts are being used. The limitation to the size of the test portion can pose the analyst with problems when the amount of material collected is large. Subsampling and preparation of a representative test portion may be difficult if homogenization is impossible or extremely expensive, or if homogenization introduces contamination. An alternative approach has been introduced in the 1990s by the development of large sample neutron activation analysis (LSNAA), later followed by large sample photon activation analysis. These techniques are capable of direct analysis of samples with masses of hundreds of grams to several kilograms. Though the principles and physics of large sample activation analysis are thoroughly understood, the method is still not as versatile or applicable as, for example, normal small sample neutron activation analysis. In this article, the physics of LSNAA is described, including methods of calibration. Examples are given of irradiation and counting facilities and the special aspects of quality control are discussed. Several examples are given of applications of large sample analysis, e.g., for studies related to electronic waste, complete archaeological and cultural artifacts, high-purity materials, and materials of irregular shape.

1 INTRODUCTION

All the routine multielemental analysis techniques (inductively coupled plasma atomic emission spectrometry (ICP-AES), inductively coupled plasma mass spectrometry (ICP-MS), and instrumental neutron activation analysis (INAA), etc.) employ rather small test portions of material, varying from a few milligrams to a few grams of solids or in the range of a few milliliters in the case of liquids (1) (see Table 1). There is even a tendency to go for smaller test portions, such as in solid-state atomic absorption spectrometry (AAS), laser-ablation ICP, and total reflection X-ray fluorescence (XRF) spectrometry. In XRF, the use of quantities larger than required to prepare the target is anyhow meaningless, as the derived information is from the surface layers, representing a few milligrams only.

The limitation to the size of the test portion can pose problems to the analyst when the amount of material collected is large. This is often the case since soils, rocks, plant material, etc. can be more easily and
representatively sampled at quantities in the order of hundreds of grams to kilograms than at quantities less than 1 g. A sample is denoted as “representative” when “it can be expected to exhibit the average properties of the material, environment or population it was taken from”.\(^{(2)}\) Representativeness is a priori preserved when (i) the sampling is performed according to specific, certified norms or when (ii) a truly homogeneous material is sampled. Homogeneity is defined as “the degree to which a property or substance is randomly distributed throughout the material”\(^{(3)}\).

Homogeneity depends on the size of the units under consideration. A mixture of minerals may be inhomogeneous at the molecular or atomic level but homogenous at the particle level. In chemical analysis this unit is obviously correlated with its effect in the conduct of the analysis (e.g. differences in solubility) or in its interpretation. Thus, both from practical and sampling considerations often more material is collected and presented for analysis than can be handled.

Irrespective of the analysis technique selected, attention has to be paid to representative subsampling to obtain a relevant final analytical portion from the originally collected material. When restricting the discussion to the analysis of solid materials, this subsampling may imply sample size reduction techniques and other processing such as sieving, crushing, milling, or blending. Problems of the following types arise:

1. Homogenization is impossible, or extremely expensive, because of material properties. Examples are electronic circuits on printed boards, household waste, and scrap from recycled electronics, automobiles, and plastics. A solution to this problem is to sort the material and to perform individual homogenizations and, subsequently, analyze, thereby increasing the total project costs.

2. The homogenization step results in contamination of the sample. Often the contamination due to crushing or milling is not controllable on every sample type. When processing a large series of samples, careful interim cleaning may get less attention since it is time consuming and therefore expensive.

Testing the degree of homogeneity is a common practice in the preparation of reference materials, but for routine operations, such a procedure, the requirement of analysis and statistical evaluation of at least five or more test portions of each sample, would raise the cost of the analysis considerably.

Considerations from the above indicate that direct analysis of the voluminous solid sample as collected might have advantages, both analytical and economical.

Detection limits in trace-element studies are based on the signal-to-noise ratio. An additional feature of analysis of large test portions is that the detection limit for trace elements may be decreased considerably in case of high-purity materials. This was demonstrated, for example, by Verheijke\(^{(3)}\) in the assessment of impurities in (5 in. diameter) silicon wafers to be used in the electronic industry.

2 LARGE SAMPLE ACTIVATION ANALYSIS

2.1 Large Sample Neutron Activation Analysis

In analytical terms, a “large sample” can be anything exceeding the regular size of a test portion in the process to determine the components of the material. The regular mass of a test portion in neutron activation analysis (NAA) varies from a few milligrams to 1 g. As already indicated, instrumental neutron activation analysis (INAA) has all the potentials to analyze, with adequate accuracy, test portions\(^{(4)}\) in the kilogram range.\(^{(5–8)}\) Both the incoming radiation for activation (neutrons) and the outgoing radiation to be measured (γ-rays) have sufficiently high penetrating power to facilitate NAA of portions of samples weighing kilograms. A “large sample” in NAA is defined as a test portion in which neutron and γ-ray self-attenuation cannot be neglected in view of the required degree of accuracy.

ACTIVATION ANALYSIS OF LARGE SAMPLES

A few phenomena need more attention in large sample neutron activation analysis (LSNAA) than in normal NAA (handling test portions varying from micrograms to a maximum of 0.5 g), where these phenomena usually have only insignificant impact to the degree of accuracy of the results. In large test portions, e.g., of kilogram size, neutron absorption and scattering result in substantial self-shielding, causing depression of the neutron flux at the center of the sample compared to the periphery. Neutron self-thermalization may cause substantial changes in the neutron spectrum throughout the sample if the sample material also contains, for example, hydrogen.

Similarly, the $\gamma$-radiation of the activation products deep inside in the sample will be more strongly absorbed and scattered before leaving the sample than the radiation resulting from, e.g., the surface of the sample; moreover the absorption and scattering increase rapidly at lower $\gamma$-ray energies. This effect is denoted as $\gamma$-ray self-attenuation. In addition, a sample of, say, 1 kg cannot be considered anymore as a more-or-less “point source” during counting at normal sample–detector distances of, e.g., 10–30 cm, resulting in a corresponding different response of the detector for the $\gamma$-radiation. In contrast to conventional INAA with small samples, analysis of test portions larger than a few hundred milligrams requires correction for these neutron self-shielding and $\gamma$-ray self-absorption effects, either via calibration or by modeling.

Trace-element determinations in large test portions have been carried out for decades in areas such as well logging, industrial (conveyor) belt analyzers, etc. using isotopic neutron sources such as $^{252}$Cf or $^{241}$Am(Be). The advantage of isotopic source-based PGNAA compared to normal NAA lies in the fact that the test portion may be analyzed locally rather than having to be taken to the laboratory and on-line information is obtained. Since the output of the sources is rather low, large samples are needed anyhow to obtain a measurable signal, usually from the main components in the material of interest. Industrial analyzers are commercially available for the on-line analysis of cement, etc., the determination of the sulfur content on coal, etc. for the detection of explosives in airline cargo, etc.

Reactor-based large sample PGNAA, i.e. using an external neutron beam, was demonstrated by Sueki et al. for a pottery sample of 15 cm diameter, 10 cm width, and 0.5 cm wall thicknesses. The neutron beam dimensions were approximately 2 cm $\times$ 2 cm.

Similar to “normal” LSNAA, in large sample PGNAA also the problems of neutron attenuation and $\gamma$-ray self-shielding have to be solved. In the example quoted above, the internal monostandard was used (see Section 5.3). Also, other intact archaeological objects were analyzed by this method, such as bronzes. Moreover, neutron beams from reactors are relatively limited in dimensions (on the order of 5 cm $\times$ 3 cm), which sets also a limit to the size of the object activated. This limitation can be overcome by repositioning the sample in the beam.

An advantage of large sample PGNA over normal LSNAA is that no special facilities have to be constructed in the reactor, and that the sample contains hardly any induced radioactivity, which is of importance when dealing with, for example, archaeological or cultural artifacts. The PGNA setup can be standard, but care has to be taken that the large object does not “transform” into a very intense source of prompt $\gamma$-radiation with associated radiation dose hazards for the researchers.
Other methods for standardization have been proposed too, and mostly are based on a priori available information on the (gross) composition of the object; e.g. using Monte Carlo simulations(26) or neutron transport codes(27) ("fixed point iteration method"). Degenaar developed a method in which no a priori information is used and the neutron self-shielding is estimated on basis of the attenuation and scattering of the neutron beam, measured outside the sample.(28)

2.3 Large Sample Photon Activation Analysis

Photon activation analysis has the potential to analyze very large samples for reasons similar to NAA: large penetration power of the incident bremsstrahlung photons (typically in the order of several tens of million electronvolts), and similar to NAA, large penetration of the γ-radiation from the induced radioactivity. There is also some similarity to prompt γ-NAA with respect to the size of the object that can be exposed at a time; here also, the sample can be "moved" through the beam to attain a homogeneous activation, or the beam can be scanned over the sample. It introduces an additional complication if the integral sample is counted after exposure: the different activated parts have different decay times but their signals are registered simultaneously. Alternatively, one may choose to limit the sample size.

At the Bundesanstalt für Materialprüfung (BAM) in Berlin, Germany, large sample photon activation analysis has been applied (29) using the 30 MeV linear accelerator for studies involving samples with sizes in the order of 8 cm height and approximately 2 cm thickness with masses of up to 100–200 g. The measurements were done using a twin detector set up; i.e. the sample was "sandwiched" between two side-looking semiconductor detectors.

One of the advantages of photon activation analysis over NAA is that the corrections for self-attenuation of the incoming bremsstrahlung photons are relatively easy to be applied on the basis of fluence rate monitors positioned before and after the sample. (29) Moreover, given the high energy of the photons, this attenuation is mostly relevant for thick targets with high average atomic number.

Large sample photon activation analysis has many interesting aspects and advantages compared to LSNAA, including its capability to detect elements such as C, N, and O, as well as Tl, Bi, and Pb. However, the number of photon activation analysis laboratories worldwide is very small and most of the large sample activation analysis studies are done with neutrons. For these reasons, this type of large sample analysis is not further elaborated upon in this article, and the reader is directed to the available literature. (29)

3 MEASUREMENT EQUATION OF LARGE SAMPLE NEUTRON ACTIVATION ANALYSIS

The basic measurement equations of NAA by which the mass of the unknown element is calculated directly demonstrates the fact that the technique does not set a priori constraints to the mass of the sample analyzed:

\[ m_{\text{unk}} = m_{\text{std}} \frac{(A_{\text{unk}})}{(A_{\text{std}})} R_\gamma R_\phi R_{\text{En}} R_\alpha R_{\text{ss}} R_\gamma R_{\text{inh}} \]  
(1)

\[ A_0 = \Phi_\text{th} \sigma_{\text{eff}} N_{\text{Av}} \theta m \frac{1}{M} (1 - e^{-\lambda t}) e^{-\lambda t} \frac{(1 - e^{-\lambda d})}{\lambda} \gamma \varepsilon \]  
(2)

in which the subscripts "unk" and "std" refer to unknown and standard, respectively, and

\[ A_0 = \text{the area of the relevant peak in the } \gamma \text{-ray spectrum, corrected for differences in decay and measurement time between the unknown (x) and the standard (s)}; \]

\[ R_\gamma = \text{ratio of isotopic abundance of the element of interest in test portion and standard (often = 1)}; \]

\[ R_\phi = \text{ratio of thermal neutron fluence rates in test portion and standard}; \]

\[ R_{\text{En}} = \text{ratio of neutron energy distribution in test portion and standard}; \]

\[ R_\alpha = \text{ratio of effective activation cross sections for the test portion and standard at the different neutron energy spectra}; \]

\[ R_{\text{ss}} = \text{ratio of the neutron self-shielding in test portion and standard}; \]

\[ R_\gamma = \text{ratio of the } \gamma \text{-ray self-attenuation in test portion and standard}; \]

\[ R_{\text{inh}} = \text{ratio of the effect of extreme inhomogeneities in test portion and standard.} \]

Also,

\[ \Phi_\text{th} = \text{the thermal neutron fluence rate (cm}^{-2}\text{s}^{-1}) \]

\[ \sigma_{\text{eff}} = \text{the effective absorption cross section (cm}^2\text{)} \]

\[ N_{\text{Av}} = \text{the Avogadro’s number (mol}^{-1}\text{)} \]

\[ \theta = \text{the isotopic abundance} \]

\[ m = \text{the mass of the irradiated element (g)} \]

\[ M = \text{the atomic mass number (g mol}^{-1}\text{)} \]

\[ \lambda = \text{the decay constant of the radioisotope formed (s}^{-1}\text{)} \]

\[ t_d = \text{the irradiation duration (s)} \]

\[ t_t = \text{the decay time (s)} \]

\[ t_m = \text{the (live time) measuring time (s)} \]

\[ \gamma = \text{the abundance in the nuclear decay of the } \gamma \text{-ray measured, and} \]

\[ \varepsilon = \text{the full energy photopeak efficiency of the detector for the energy of the } \gamma \text{-ray measured.} \]
Many of the correction terms, \( R_i \), can often be neglected in normal sample analysis but some of them like \( R_{\text{neu}}, R_{\gamma \text{att}}, R_{\gamma \text{mtt}}, \) and \( R_{\text{inh}} \) become significant in large sample analysis. As such, algorithms in large sample NAA differ from normal NAA by the calculation/estimation of:

- the neutron self-shielding and/or neutron fluence rate profile inside the test portion,
- the \( \gamma \)-ray self-attenuation,
- the volumetric photopeak source efficiency of the detector, and
- the impact of extreme inhomogeneity effects.

There are many approaches for these calculations, varying from pure theoretical modeling\(^9\), Monte Carlo modeling\(^{20}\), and modeling using a priori available information about the test portion composition\(^7\) to pragmatic empirical estimations of the correction factors\(^{17}\). Modeling may even be avoided when, e.g., for routine applications a representative well-characterized (large sample) standard – even a reference material – is available\(^{18}\). These standardization methods are further discussed below.

### 4 INSTRUMENTATION

#### 4.1 Neutron Sources for Large Sample Activation Analysis

The type and strength of the neutron source and energy characteristics play an important role in any type of NAA including LSNA. As the radioactivity produced is directly proportional to the neutron flux (\( \phi \)) and energy-dependent neutron absorption cross section (\( \sigma \)). The neutron source should provide a sufficiently high neutron fluence rate so as to keep the product of neutron fluence rate and large test portion mass almost equal to that in small test portion NAA. This criterion indicates that for test portions with masses in the order of 2 kg a neutron fluence rate of approximately \( 5 \times 10^{12} \times 0.2/2000 = 5 \times 10^8 \text{ cm}^{-2} \text{s}^{-1} \) would result in an adequate induced radioactivity during the irradiation time, similar to that applied in conventional NAA in which a 200 mg test portion is processed. Fluence rates on the order of \( 10^8 \text{ to } 10^9 \text{ cm}^{-2} \text{s}^{-1} \) are found at an extended distance from the core of small and medium-sized reactors\(^{15}\), in beam tubes, and in thermal columns (TCs).\(^{15,19,20}\) However, low fluence rates can also be realized – or even may be preferred – by lowering the reactor power because of fuel economy considerations.\(^{30}\) Table 2 also provides an indication of typical neutron sources available to provide the required neutron fluence rate.

</tbody>
</table>

(Mass \times \text{ flux}) = constant = 200 mg \times 10^{13} \text{ cm}^{-2} \text{s}^{-1}

The advantage of reactor TCs above, e.g., poolside facilities, is that the longitudinal neutron flux gradient (i.e., horizontally away from the reactor core) over the sample is much less steep because of the multiple neutron scattering in the graphite inside the TC, as can also be derived from the differences in thermal neutron diffusion length in carbon and water, viz., 64.2 and 2.76 cm, respectively. Rotating the sample along its vertical axis compensates partly for these gradients. However, in some materials the neutron self-attenuation combined with the neutron flux gradient may result in situations in which the center of the test portion is hardly activated compared to the periphery. In such cases, the measured \( \gamma \)-rays originate mainly from the periphery and the analysis result will apply merely to the outermost layers of the sample rather than reflecting the bulk composition. In such facilities, the approach is to set limits to the dimensions of the test portion. Moreover, neutron self-moderation will occur owing to the less thermalized neutron spectrum in poolside facilities, resulting in difficulties in the calculation of the element amounts.

Neutron fluence rates \(<10^{10} \text{ cm}^{-2} \text{s}^{-1} \) may also be attainable with isotopic neutron sources and high-intensity neutron generators, and in (reactor-based) external neutron beams. \(^{252}\text{Cf} \) is probably the most attractive isotopic neutron source from the point of view of the neutron spectrum shape and easy thermalization aspects. However, the short half-life (2.64 years) may be seen as an economical disadvantage. Other isotropic neutron sources have a relatively hard neutron spectrum, resulting in relatively low thermal neutron fluence rate equivalents. The applicability of such neutron sources may, therefore, be limited to the determination of the major components in a sample.

Neutron generators (3–14 MeV) have their own scope of applications.\(^{31,32}\) One of the problems in using neutron generators and isotopic neutron sources is that the neutron fluence is anisotropic and therefore the neutron flux seen by a large sample is not the same in all parts of the sample. This can be overcome to some extent by rotating the test portion during irradiation. Given the fact that the thermal neutron fluence rate in, e.g., a D-D
(deuterium ions on a deuterium target) generator is of the order of $10^4$ lower than in research reactors, an increase in sample mass of at least $10^6$ (i.e. from 200 mg to 2 kg) would be needed to compensate for this low thermal fluence rate.

An advantage of large (kilogram size) sample NAA with D-D generators over reactors is that the sample may be quickly removed from its irradiation position upon shutting down the accelerator, facilitating the measurement of radionuclides with short half-lives. For samples in the order of tens of grams, pneumatic facilities may be designed. Larger sample masses may also be considered for delayed neutron counting procedures to reach lower minimum detectable amounts, although this implies that a larger delayed neutron counter is needed too.

However, several technological obstacles exist both with isotopic neutron sources as with neutron generators, such as the large void needed within the moderator of the device. Moreover, since these moderators are often based on hydrogenous materials such as polyethylene or paraffin, steep flux gradients may occur over the sample, similar to those outlined earlier for poolside reactor facilities. The large sample approach may also be considered for irradiation with the sub-fast neutrons, although here an increase in sample mass from, e.g., 200 mg to 200 g might be sufficient for reaching the sensitivity required. However, an additional problem is that large sample masses will increase the effect of neutron self-moderation.

Most of the external neutron beams from nuclear reactor, with neutron fluence rates of $10^6$–$10^8$ cm$^{-2}$ s$^{-1}$, are suitable for PGNAA. An advantage associated with PGNAA is the flexibility in choosing the mass and shape of the test portion. However, one should be careful in increasing the test portion mass, as it might adversely affect the measurements because the background is sample dependent in PGNAA. It becomes severe particularly in the cases where the hydrogen or boron fraction in the large test portion is high, as it results in an extremely intense source of prompt $\gamma$-radiation, which will affect the results. External neutron beams of isotopic neutron sources have usually neutron fluence rates of $<10^7$ cm$^{-2}$ s$^{-1}$ and can in principle be used for PGNAA, though the energy definition becomes a tedious problem. Steep neutron gradients over the sample occur in neutron beam activation analysis too.

4.2 Irradiation Facility

Transferring the test portions to the irradiation position of the neutron source is usually done with pneumatic/hydraulic transfer facilities and/or manually or automatic loading facilities. Most of the pneumatic facilities are designed to handle volumes up to 5–50 mL, which are placed in a sample carrier known as “rabbit”. Use of rabbit systems places constraints on the sample shape so as to maintain the defined geometry. In principle, it is possible to transfer test portions up to 1 kg or more through such facilities – such big systems already exist for transferring documents in offices and banks; however, it is yet to be explored and examined whether large rabbits can be obtained with the required specifications (quality of the rabbit materials, purity, and radiation/mechanical resistance) for application in reactors.

In some reactors TCs are available for accommodating a large sample irradiation facility (see Figures 1 and 2). Samples are placed in the irradiation position of the TC by the mechanical movement of a tray that houses the sample in a defined position. In Table 3, suggestions for facilities for irradiation of test portions of different masses are indicated.

There are various design aspects to be taken into account for irradiation facilities:

1. A large-volume facility near the core of a nuclear reactor creates a void in the reactor’s reflector, whereas loading and unloading may cause unwanted fluctuations in the core’s reactivity. Moreover, a high amount of Ar will be produced from activation of the air in the container.

2. The thermal neutron fluence rate gradient in the water reflector of a light-water-moderated reactor is quite steep, typically by a factor of 3 per each 3 cm, which is due to the neutron diffusion length (2.84 cm) in water. Such a strong gradient would also create an unwanted strong flux variation over the large test portion to be activated. This may be corrected for by rotating the sample during counting, by mixing the sample after irradiation, or by the use of in situ relative efficiency method. Mixing, however, eliminates information about inhomogeneities. The problem of heterogeneity may also be addressed by dividing the large test portion into many smaller fractions, to be processed individually followed later on by combining of the results.

3. Large hydrogen mass fractions may result in neutron spectrum changes over the test portion volume due to self-thermalization. This phenomenon is difficult to correct for mathematically, and may be an additional reason to consider an irradiation facility with well-thermalized neutron spectrum, for instance, to be realized in a TC.

4. Large sample activation facilities at isotopic neutron sources must be designed in such a way that adequate shielding is ensured against the prompt $\gamma$-rays, which will be several orders of magnitude higher than with normal small samples.
A few of the large sample NAA reactor facilities that are currently operational are given in Table 4.\textsuperscript{[35]} Large sample PGNAA facilities have been realized in Hungary and Japan. Isotope neutron source-based large sample PGNAA facilities are in use in some places.\textsuperscript{[36]}

4.3 Sample Containers for Irradiation

The large sample container itself may be of any shape and type. A wide-neck bottle is easy to fill when coarse material has to be analyzed (Figure 3).\textsuperscript{[5]} A container of inexpensive plastic may be preferred, as the impurities in the plastic itself (blank contribution) may be neglected at a given sample size (see Table 5). If the contribution from the sample holder is substantial, the irradiated large samples may also be easily transferred after irradiation into nonirradiated containers and possible small losses during transfer can be neglected in view of the large mass of the test portion. As such, a Marinelli beaker geometry or multisample container (Figure 4)\textsuperscript{[37]} may
4.4 Counting Facility

Very large Ge detectors are available (crystal sizes up to 400–800 cm³, comparable to “relative efficiencies” of 100–200%). Such big detectors are an additional tool to maintain adequate sensitivity in NAA. Side-looking detectors (“horizontal dipstick”) have the advantage that cylindrical samples, positioned perpendicular to the detector axis, can easily be rotated around the sample axis to reduce geometrical effects. Vertical dipstick detectors have the advantage to measure large samples in the Marinelli beaker geometry. Well-type Ge detectors can handle test portion volumes of up to approximately 8 mL, and thus have their own niche in large sample NAA, especially as an addition to enhance sensitivity for test portions in the grams range.

In general, it is preferable to count the large sample by placing it at a certain distance from the detector end cap to minimize complications in the efficiency calculations, in particular in the coincidence summing corrections. The distance between the test portion and detector is guided by the sample activity; the higher the activity, the farther the sample to be placed from the detector. Automatic sample changing can be realized irrespective of the sample size. Sample changers are already commercially available for containers with volumes up to 1 L, although they have been designed for the Marinelli beaker measurement.

Adequate shielding of the stored samples remains, of course, a prerequisite.

Different detector calibration approaches are needed—taking into account voluminous photo peak efficiency, $\gamma$-ray self-attenuation, and coincidence summing correction if Marinelli beaker geometries or multisample containers are applied. In the multisample container setup, as the geometry for each container is the same, one can start with one container and measure up to 20 samples according to their decay.

The spectrometer may have to be equipped with a separate device to allow the determination of the effective $\gamma$-ray linear attenuation coefficients using a multi-$\gamma$-ray pencil beam of an external source (e.g. $^{152}$Eu). An example of such a setup is given in Figure 5.

It may be necessary to collimate the detector in case the localization of the inhomogeneity is the subject of interest in large sample analysis (see Figure 6). Such a setup will allow, in principle, for emission tomography of the activated sample.\(^\text{(38)}\)

More advanced spectrometer systems may be designed, in which two or more Ge detectors surround the large sample to create nearly $4\pi$ geometry of the detectors.\(^\text{(29)}\)

The individual spectra can be added later to create a composite spectrum with better statistics.

The $\gamma$-ray spectrometer should be equipped with dedicated high-count-rate electronics if the induced radioactivity to be measured would result in a count rate $>20000 \text{s}^{-1}$. The prerequisites are a transit–reset preamplifier and pulse processing electronics (analog or digital), allowing for on-line dead-time compensation, e.g., based on the loss-free counting principle.\(^\text{(39)}\) The latter is relevant only if count rates vary significantly during the counting time, as may be the case in counting radionuclides with very short half-lives (in the range of seconds to several minutes).

It is interesting to take note that there are a few applications where counting could be carried out using well-type scintillation detectors. In the cases where major components only have to be analyzed and the neutron sources are isotope based, then the resulting activity could be low and the $\gamma$-ray spectra might be relatively simple, which could be measured using high-efficiency scintillation detectors. Large sample NAA with isotopic sources and the use of scintillation detectors may be considered as an additional opportunity to further enhance the sensitivity. One may even construct a simple $4\pi$ detector by putting two well-type detectors against each other.

5  CALIBRATION

Determination of the elemental masses in large sample NAA may be done as in small sample NAA, via

- the absolute method,
- the comparator method, or
- the internal standard method.

5.1 Absolute Method

The absolute method for standardization in NAA is based on using known values for neutron fluence rate and activation cross sections, derived either from previously performed measurements or from reactor physics estimations (neutron fluence rate) and from the literature data (cross sections); the same is the case with $\theta$, $N_{AX}$, $M$, $\sigma_{eff}$, $\gamma$, and $\lambda$. For many (n,γ) reactions and radionuclides, the parameters $\sigma_{eff}$, $\gamma$, and $\lambda$ are not precisely known, while in some cases $\theta$ also is not known accurately. Since the various parameters are often achieved via independent methods, their individual imprecisions will add up in the calculation of the elemental amounts, leading to large systematic errors. This method is best applicable if the composition of the sample matrix is well established in advanced, as is the case, e.g., when dealing with pure materials. It is well known that even in normal NAA this approach may not yield highly accurate data but still the results may be adequate.
for the intended purpose. Still, additional estimates are needed for correcting the neutron fluence rate gradient and the γ-ray self-absorption. The first may be done using simplified models or using neutron transport codes, and the second after simple transmission measurements or using tabulated linear attenuation coefficients in case the sample is well defined with respect to its composition.

5.2 The Comparator Method

The test portion is irradiated together with a calibration sample containing a known amount of the element(s) of interest. The calibration sample is measured under (preferably) the same conditions as the sample (sample-to-detector distance, sample size, and if possible composition). From a comparison of the net peak areas in the two measured spectra, the mass(es) of the element(s) of interest can be calculated (see above, Equations (1) and (2)):

\[
\text{mass}_\text{unk} = \text{mass}_\text{std} \left( \frac{A_{\text{0,}\text{unk}}}{A_{\text{0,}\text{std}}} \right) R_\gamma R_\theta R_\text{En} R_\sigma R_\text{ss} R_\text{inh} R_\text{eff} R_\text{inh} \tag{3}
\]

The relative standardization based on element standards is not immediately suitable for laboratories aiming at the full multielement powers of INAA. It is virtually impossible to produce a multielement standard containing known amounts of all 70 detectable elements with sufficient accuracy in a volume closely matching the size and the shape of the samples. For this reason, some laboratories prefer to use (certified) reference materials as a multielement standard. However, if dealing with large samples (gram to kilogram size), the use of (certified) reference materials is not practical (major differences in neutron exposure, γ-ray attenuation, and volumetric counting efficiency between comparators and samples all have to be accounted for. In normal NAA, most of these differences can be neglected, also because the comparators are co-irradiated with the samples. But in LSNAA this may be practically impossible; the irradiation facility may not be spacious enough, and substantial difference may exist in the neutron exposure and flux gradients. Only if the neutron flux spectrum is well known – as in TCs – and the neutron fluence rate gradient can be established in each individual test portion, the comparator method provides an opportunity for applicability. In that case, even the \( k_0 \)-based method for standardization may be applied.

The comparator method is, however, very well usable for large sample analysis of, e.g., large liquid samples such as water or oil since standard samples with element spikes into a similar matrix can easily be prepared.

5.3 Single Comparator Method

Originally, the single comparator method for multielement INAA was based on the ratio of proportionality factors of the element of interest and of the comparator element after correcting for saturation, decay, counting, and sample weights. Girardi et al.\(^{(40)}\) defined the \( k \)-factor as

\[
k = \frac{M_\gamma c \gamma \theta c \sigma_{\text{eff,c}}}{M_\epsilon c \gamma \theta t \sigma_{\text{eff,t}}} \tag{4}
\]

in which the subscripts "t" and "c" refer to the element of interest in the sample and comparator, respectively. Mass fractions can then be calculated from these \( k \)-factors; for an element determined via a directly produced radionuclide, the mass fraction \( \rho \) follows from

\[
\rho = \frac{(A/\text{SDCw})_t}{(A/\text{SDCw})_c} \cdot k \tag{5}
\]

where \( S = (1 - e^{-\lambda t \gamma}) \)

These experimentally determined \( k \)-factors are often more accurate than those calculated on basis of literature data as in the absolute standardization method. However, the \( k \)-factors are valid only for a specific detector, a specific counting geometry, and the irradiation facility and remain valid only as long as the neutron flux parameters of the irradiation facility remain stable.

The main problem of the single comparator method in LSNAA is that differences in neutron exposure, γ-ray attenuation, and volumetric counting efficiency between comparators and samples all have to be accounted for. In normal NAA, most of these differences can be neglected, also because the comparators are co-irradiated with the samples. But in LSNAA this may be practically impossible; the irradiation facility may not be spacious enough, and substantial difference may exist in the neutron exposure and flux gradients. Only if the neutron flux spectrum is well known – as in TCs – and the neutron fluence rate gradient can be established in each individual test portion, the comparator method provides an opportunity for applicability. In that case, even the \( k_0 \)-based method for standardization may be applied.

The comparator method is, however, very well usable for large sample analysis of, e.g., large liquid samples such as water or oil since standard samples with element spikes into a similar matrix can easily be prepared.

5.4 \( k_0 \)-Based Method for Standardization

At the Institute for Nuclear Sciences in Ghent, Belgium, an attempt has been made to define \( k \)-factors that should be independent of neutron flux parameters as well as spectrometer characteristics.
The expression for the activation reaction rate can written as

$$ R = \Phi_{th} \sigma_0 + \Phi_{epi} I_0(\alpha) $$

(6)

The ratio $f$ of the thermal neutron flux and the epithermal neutron flux is $f = \Phi_{th}/\Phi_{epi}$ and the ratio of the resonance integral and the thermal activation cross section can be expressed as $Q_0(\alpha) = I_0(\alpha)/\sigma_0$; thus the effective cross section is

$$ \sigma_{eff} = \sigma_0 \left(1 + \frac{Q_0(\alpha)}{f}\right) $$

(7)

The $k_0$-factor is now defined as

$$ k_0 = \frac{1 + (Q_{0,c}(\alpha)/f) \varepsilon_c}{1 + (Q_{0,t}(\alpha)/f) \varepsilon_t} \frac{M_c \varepsilon_0 \gamma_{c}}{M_t \varepsilon_0 \gamma_{t}} $$

(8)

and the mass fraction, again for an element determined via a directly produced radionuclide, is found from

$$ \rho = \frac{1 + (Q_{0,c}(\alpha)/f) \varepsilon_c}{1 + (Q_{0,t}(\alpha)/f) \varepsilon_t} \frac{(A/SDC)_c}{(A/SDC)_t} \frac{1}{k_0} $$

(9)

The $k_0$-factor has thus become a purely nuclear parameter for the thermal neutron spectrum. In the $k_0$ convention, Au is proposed as the comparator element. The neutron flux parameters $f$ and $\alpha$ no longer cancel out in concentration calculations and must be measured in each irradiation facility, preferably even for each irradiation and sample. The $k_0$-factors are used in Delft for the analysis of very large samples.

5.5 Internal Monostandard Method

In the internal monostandard method, one of the radionuclides produced during activation of the test portion is used as monostandard. The rationale behind this is that the effect of neutron spectrum perturbation is the same for this parent element of this radionuclide as well as for all other elements in the sample; as such there is an implicit assumption that the test portion is “macroscopically” homogeneous.

In the case of internal monostandard method using TC irradiations followed by $\gamma$-spectrometric method, the ratio of mass $(m)$ of an element $(x)$ in the test portion $(t)$ to mass of the internal comparator element $(c)$ in the sample is given by Equation (10):

$$ \frac{m_t}{m_c} = \frac{(S.D.C) \cdot (f + Q_c(\alpha))_t}{(S.D.C) \cdot (f + Q_c(\alpha))_c} \frac{A_{Al}}{\varepsilon_0 \gamma_{c}} \frac{1}{k_{0,c}(x)} $$

(10)

Here, $k_{0,c}(x)$ represents the relative sensitivity of element $x$ with respect to $y$ and is calculated from the $k_{0,Au}$ factors in the literature.

The internal monostandard method either results in elemental mass ratios (element of interest vs. monostandard element) and thus may serve for comparative studies, or, in the case of, e.g., materials of high purity and known stoichiometry, directly into mass fractions of the elements of interest if (one of) the major component(s) is used as the monostandard element.

5.6 Neutron Fluence Rate Monitoring

Neutron fluence rate monitoring is needed for the $k_0$ method of standardization and may be done noninvasively with the flux monitors outside the sample, as well as by inserting flux monitors inside the sample. The first approach may use, e.g., the neutron depression outside the large sample to estimate the neutron flux distribution; the second approach provides direct information on the flux distribution. The first approach is applied in Delft for large sample irradiations in the reactor’s TC. During the irradiation, the sample is surrounded by four flux monitors at any desired height around the sample. Since the unperturbed neutron flux gradient in the TC can be derived from the irradiation of a pure graphite sample, the neutron flux depression outside the sample can be estimated (Figure 7). This forms the basis for estimating the effective neutron diffusion length and neutron diffusion coefficient. Finally, the overall correction factor is calculated – which reflects how the large sample compares to a small sample – using the volume efficiency of the Ge

Figure 7 Neutron flux depression outside a large sample placed inside the graphite-filled thermal column. The curve A indicates the unperturbed flux gradient; curve B schematically shows the flux gradient if a sample absorbing and scattering thermal neutrons is placed in the irradiation position.
detector, the neutron diffusion length and coefficient, and the effective linear attenuation coefficients.

Changes in the neutron spectrum due to self-thermalization are much more difficult to deal with, as these are not easy to monitor. The extent of this effect depends, of course, on the neutron spectrum shape and the fraction of epithermal and fast neutrons compared to the thermal neutrons. In TC facilities, the ratio of thermal over nonthermal neutrons may be much larger than a factor of 1000, eliminating the significance of neutron self-thermalization. The user of the irradiation facility should be familiar with this phenomenon, and a priori information must always be collected about the sample composition so as to estimate the extent of these effects and to decide if empirical correction factors can be applied or if additional in situ monitoring is needed (i.e. invasive, by inserting suitable monitors inside the sample).

5.7 \( \gamma \)-Ray Self-Attenuation

The \( \gamma \)-ray self-attenuation correction is relatively easy to establish once the effective linear attenuation coefficients are available, either by measurement or by calculation from the approximate (or well-known) elemental composition. A multi-\( \gamma \)-ray emitting source, with \( \gamma \)-ray energies distributed over the entire range of interest (such as \( ^{152} \text{Eu}, ^{182} \text{Ta} \)) can be used for this. A nearly pencil beam geometry can be created by locating this source behind a pinhole collimator, and the \( \gamma \)-ray transmission can be measured at several heights along the sample. This forms the basis for the estimation of the effective linear \( \gamma \)-ray attenuation coefficients.

The volumetric photopeak efficiency can be determined by Monte Carlo modeling, but this requires precise information about the inner geometry of the cryostat and detector configuration (including the dead-layer thickness). Empirical curves may be determined using standard sources in water, as the self-attenuation can simply be subtracted from the measured efficiency. In situ relative detection efficiency in a voluminous sample was determined using the multi-\( \gamma \)-emitters produced in the sample, and was adequate to calculate mass ratios with respect to the comparator using Equation (5).

Pragmatic approaches have been suggested in which the large sample, after activation, is repacked into many small-diameter containers that are placed in a cylindrical holder surrounding the detector. If the detector crystal is perfectly symmetrically mounted inside the cryostat, the detection efficiency for each of the positions around the detector is the same, which simplifies the calculations. Besides, the dimensions of the small containers can be chosen such that \( \gamma \)-ray attenuation effects may be neglected.

It should be noted that the \( \gamma \)-ray spectrum due to the natural radioactivity of the sample material has also to be measured in large sample analysis, prior to the activation. These “sample background” peaks in the \( \gamma \)-ray spectrum should be separately treated later on in the neutron and \( \gamma \)-ray self-attenuation corrections.

5.8 Extreme Inhomogeneities

Combination of correction algorithms for neutron and \( \gamma \)-ray self-attenuation as well as for the volumetric photopeak efficiency yields an “overall correction factor”, which reflects the difference between the actual detector response for a given \( \gamma \)-ray energy and the theoretical detector response if the sample were a massless point source located in the large sample’s center, without any neutron and \( \gamma \)-ray attenuation.\(^{9} \)

In these corrections, it is assumed implicitly that both trace elements and major (matrix) elements in the sample are homogeneously distributed on a macroscopic scale. If this condition is not met, there is a high probability that owing to the neglect of inhomogeneities the concentrations determined are not correct. How large these deviations may be as a result of such neglect has been studied via computer simulations. Inhomogeneities may influence the results of the irradiation as well as of the measurement; therefore, both have been treated separately. Inhomogeneous matrix composition has been modeled by composing a sample of cylinders with strongly differing neutron or \( \gamma \)-ray attenuation properties. Inhomogeneity for trace elements has been simulated by modeling extreme distributions of a trace element with either neutron or \( \gamma \)-ray attenuation properties, strongly differing from those of the main composition of the sample.\(^{20,46} \) Both inhomogeneities in matrix composition (e.g., layered structures) and trace-element inhomogeneities (e.g., “hot spots”) were taken into account.

Obviously, the results of these simulations demonstrated that false concentrations may be obtained if inhomogeneities are not accounted for in the interpretation step of large sample INAA. The smallest errors may occur for matrix inhomogeneities; the most pronounced effects can be expected when the trace element of interest is distributed either on the outside or on the axis of the cylindrical sample.

In these simulations, materials or elements were selected with neutron and \( \gamma \)-ray attenuation properties that were strongly different from the rest of the sample; as such they may be considered as “extremities”, and the consequences on the inaccuracy of the results rather indicate “worst case” conditions.
5.8.1 Determination of Inhomogeneities

The presence of extreme inhomogeneities in large samples may be considered a nuisance. On the other hand, large sample analysis is a unique tool for determining these inhomogeneities without destroying the test portion. To this end, sample scanning using a collimated detector has been introduced, and it is assumed that the sample consists of volume elements that individually are considered homogeneous.

The set of spectra constituting one scan is statistically evaluated to determine whether fluctuations over the scan of the count rates of $\gamma$-rays of a given energy are only due to Poisson counting statistics or are also due to inhomogeneities in the sample. If inhomogeneities have only a layered structure in the direction of the cylinder axis of the sample, the sample can be analyzed layer by layer, and for the most extreme cases the analysis can be performed for each voxel separately. An example of a collimated detector system for large sample scanning is shown in Figure 6.

Baas et al.\(^\text{38,47}\) developed a method for the detection of local inhomogeneities. The count rate in each channel of each segmented measurement can therefore be compared with the average count rate in each channel after summing all individual measurements. Such a comparison, taking into account uncertainties, is made analogous to the $\zeta$-score principle. Values of $|\zeta| > 2$ or $ > 3$ (depending on the analyst’s fitness-for-purpose criterion) indicate a local inhomogeneity at the respective $\gamma$-ray energy in a particular voxel. This approach is visualized in Figure 8. A bottle of approximately 25 cm length and 8 cm diameter filled with soil was irradiated in the large sample facility in Delft. The induced radioactivity was measured with a 96% Ge detector, collimated with a 10-cm-thick Pb collimator with a 2-cm split opening. The figure shows the $\zeta$-scores for each channel number ($\gamma$-ray energy) along the height of the sample. From the zoomed details it can clearly be seen that strongly deviating $\zeta$-scores occur at, e.g., 439 and 1115 keV, indicating an inhomogeneity for zinc. In addition, the histogram of all $\zeta$-scores in this figure provides also an insight into the presence of this inhomogeneity.\(^\text{47}\)

6 QUALITY CONTROL

The high degree of accuracy in normal activation analysis results from decades of experience in the development of certified reference materials. Many sources of error and the quantification of their impact are known.\(^\text{48,49}\) Methods commonly referred to as quality control practices have been developed to inspect the occurrence of errors during the analysis, whereas implementation of quality assurance contributes to minimizing and even avoiding the occurrence of errors. The known sources of error in normal activation analysis may occur in large sample analysis too. Some of them – such as $\gamma$-ray self-attenuation and neutron/photon fluence rate, or neutron spectrum gradients – have much larger effects. Extreme inhomogeneities are an additional phenomenon in large sample analysis,\(^\text{46}\) with an impact on the degree of accuracy.

Quality control in normal activation analysis includes the simultaneous analysis of well-characterized quality

---

**Figure 8** Energy- and position-correlated $\zeta$-scores (see text) of measured radioactivity, indicating location of inhomogeneities in a sample of 20 cm height and 10 cm diameter.
control samples, blanks, and sometimes duplicates. In addition, inspection of the intensity ratios of γ-ray peaks of a given nuclide and/or the quantified results based on different radionuclides formed from a given element also provide a unique opportunity to inspect for errors. The applicability of these quality control approaches for samples of increasing mass is given in Table 6.

It is clear that basic problems emerge when extending the traditional approaches to samples with weights of more than a few grams. Firstly, well-characterized control samples of the size of large samples (several grams to kilograms) are either very expensive to use or not available at all. Secondly, large sample analysis may be required because of the heterogeneity of the object, which cannot be simulated by a control sample even if it were available. Thirdly, duplicates – assuming identical composition in mass fraction and in degree of homogeneity – may probably not be available when larger sample masses are needed. The problem related to the blank – impurities in the sample container and/or contamination – has, on the contrary, a smaller impact on the final result since the increase in the ratio of sample mass to container mass may result in negligible contribution of the blank (Table 5).

New strategies have to be developed to control the analytical quality in large sample analysis. One of the opportunities is to continue with the use of performance indicators, derived from the actual sample analyzed. In fact, this is not different from most quality control procedures in, e.g., manufacturing and production, in which the quality of a final product depends on predefined specifications being met, such as dimensions, tolerances, mass, color, or operation characteristics. The inspection of γ-ray intensity ratios and the use of different radionuclides of one element are already examples of such a form of quality control in activation analysis. This approach can further be extended to other sample/material characteristics on the basis of physical sample properties such as γ-ray self-attenuation and neutron attenuation parameters, as well as via the degree of inhomogeneity (Table 3).

### 6.1 Quality Control in Large Sample Analysis

Some materials may be difficult to be processed to such homogeneity that representative subsamples can be taken at the <1 g level. For such materials, it may be advantageous to analyze much larger quantities without homogenization and to assume that the inhomogeneities are randomly distributed throughout the sample, so that the entire quantity can be considered as homogeneous. However, this assumption has some limitations. Overwater and Bode demonstrated the impact of extreme inhomogeneities on the correction mechanisms for the attenuation of γ-ray attenuation and neutron self-shielding. Inhomogeneities with strong γ-ray absorbing properties have stronger effects on the degree of accuracy than those with strong neutron absorbing properties. It is therefore relevant to inspect for the presence of such extreme inhomogeneities in order to decide on the value of the finally calculated mass fractions. Two opportunities to inspect such inhomogeneities are given here.

Y = yes, application possible; N = no, not possible; l.r. = less relevant (see text); n.r. = not relevant.
Additionally, the methods developed by Baas et al. (described in the preceding text) can be used for the detection of local inhomogeneities. It can now be decided on a case-to-case basis whether such inhomogeneities have any unwanted impact on the final analysis result.

The correction for neutron self-shielding in LSNAA may be made using information derived from the neutron fluence rate depression at positions in the irradiation facility just outside the sample. Overwater and Hoogenboom developed this approach to estimate the thermal neutron diffusion length $L_s$ and the thermal neutron diffusion coefficient $D_s$, which subsequently were used to reconstruct the neutron fluence rate profile inside the large sample. Both $L_s$ and $D_s$ are physical element properties and, similar to the effective linear $\gamma$-ray attenuation coefficient, boundaries can be estimated for the values of these two parameters in real materials. Though strongly correlated ($L_s = D_s/\Sigma_a$, with $\Sigma_a$ the macroscopic absorption cross section ($\text{cm}^{-1}$)), typical values are $\sim 1 \text{ cm} < L_s < \sim 20 \text{ cm}$ and $\sim 0.2 \text{ cm} < D_s < \sim 3 \text{ cm}$. An example is given in Figure 4. A $\sim 1$-m long, $\sim 15$-cm diameter water basin sediment drill core was analyzed in the frame of a pollution research project. Zinc foils were used as neutron flux monitors. The monitors were positioned just outside the sample container to monitor neutron fluence rate depression by comparison with the neutron fluence rates as monitored in a separate irradiation with a solid graphite sample, thus simulating the unperturbed neutron flux. The calculated values of $L_s$ and $D_s$ at different heights are plotted within the bandwidths for these values (Figure 11). Also, the average neutron fluence rates as a function of sample height is given. The fluence rates can be fitted with a cosine function, reflecting the flux distribution within the reactor’s TC.

Assuring the quality of the results requires insight, monitoring, and control of the sources of error. Quality control procedures as traditionally applied in chemical analysis are not fully applicable in large sample analysis. One of the advantages of activation analysis is that some of the measured sample parameters dealing with $\gamma$-ray and neutron attenuation can only vary in ranges set by well-known values of elemental constants. These parameters can be much more easily determined in large sample analysis than with samples in the milligram range, thereby offering an outlook for direct verification of the quality of the related correction algorithms.
7 SENSITIVITY

Sensitivity is defined as the gradient of the response curve; i.e., the change in instrument response that corresponds to a change in analyte concentration. This definition translates in INAA into the net peak area as a function of the analyte mass. Larger peak areas at a given sample mass can be obtained by the following:

- higher neutron fluxes and longer irradiation times
- more efficient detectors
- larger sample masses.

Higher neutron fluxes and longer irradiation times are often not easily attainable, as the first is limited by reactor design, whereas longer irradiation times only have a positive effect on the sensitivity for radionuclides with very long half-lives.

Absolute photopeak efficiencies of detectors of different sizes and for different geometries are given in Table 7, and a comparison of the absolute efficiencies of a regular 17% coaxial and one of the largest well-type detectors reported in the literature\(^{51,52}\) is given in Figure 12. It should be noted that the use of Compton suppression shields does not result in an increase in sensitivity – as often erroneously suggested; after all, the signal resulting from the induced radioactivity does not increase and sometimes even decreases due to summing-out effects or larger sample-detector distances. Compton suppression systems find their advantage in a decrease in uncertainty of measurement due to decrease of the background under a peak.

Large sample masses can compensate for low neutron fluxes. As the limiting factor in NAA is merely the maximum acceptable induced radioactivity upon counting, a comparison has been made with normal INAA in which a hypothetical 200-mg sample is irradiated for a given time at a neutron flux of \(10^{13} \text{ cm}^{-2} \text{s}^{-1}\). Assuming a certain neutron fluence rate and a cylindrical sample of similar length and diameter, and an average density of 0.5 g cm\(^{-3}\), a first estimate can be made of the minimum
mass needed to reach the same sensitivity as for the small sample at a high neutron fluence rate (Table 8). However, these results must be corrected for the losses due to neutron self-shielding and \( \gamma \)-ray self-attenuation, and the fact that the center of voluminous samples, simply for physical reasons, is always positioned further away from the detector than in case of a small sample. In Figure 13 these effects have been combined, and it can be derived that at a given neutron fluence rate a net gain in signal of a factor of 10 can be obtained by increasing the sample mass by a factor of 15 (e.g., from 200 mg to 3 g).

### 7.1 Natural Background

A large sample NAA procedure should start with measurement of the natural radioactivity of the sample, as the corresponding peaks in the \( \gamma \)-ray spectrum should be separately treated later on in the neutron and \( \gamma \)-ray self-attenuation corrections.

### 8 APPLICATIONS

LSNAA has evolved over the years towards a capability for various samples types that otherwise would have been difficult to analyze. Accordingly, the developments faced many challenges, each one different from the other, and in this process its horizon of application to various fields has increased: e.g., nutritional studies, geology, biology, archaeology, waste analysis, high-purity material characterization, precious samples, and liquid samples, from all walks of life. A few of them are given in the following text.

#### 8.1 Materials Difficult to Homogenize: Geological Samples, Ores, and Waste

LSNAA is highly suitable for the analysis of heterogeneous geological material such as rocks, coal (determination of quality), ores, and mineral concentrates. Conveyor belt monitoring of elemental concentrations by PGNAA in coal and cement raw materials has led to an increased efficiency of coal-fired power plants and cement factories. It appears that this technique has the required potential to trigger industrial processes and gives reliable results.

Waste material in many cases is considered to contain hazardous substances whose behavior could result in their entry into biosphere through the atmosphere or ground water. Therefore, appropriate classification of the waste material is required in order to ensure safe disposal or further treatment and recycling. Construction material, domestic and electronic waste, as well as contaminated sediment and compost material are considered to be highly heterogeneous and therefore elaborate sampling procedures are required if representative sampling of these materials for analysis is needed. LSNAA has been effectively used to analyze large samples of soil, electronic waste, and other materials. These are the materials in which both subsampling and homogenization, steps not required in LSNAA, are very difficult and cost intensive. A typical example is the elemental composition analysis of waste from an incineration plant. This type of
sample cannot be easily homogenized and analyzed by other analytical techniques. However, a 1-kg portion of this waste was analyzed by using the LSNAA without homogenization.

8.2 Materials That May be Contaminated During Homogenization: High-Purity Materials

LSNAA is an extremely useful technique to analyze the metals and alloys for impurities. It is being used to analyze various finished products of alloys (Zircaloy 2, Zircaloy 4, SS-316M (stainless steel), and 1S aluminum) that are used in reactor technology\(^\text{56}\) and for impurities in high technological materials such as silicon and superalloys.\(^\text{53}\) The biggest advantage is that information is obtained on the entire specimen, and because of the absence of subsampling, contamination can be minimized.

8.3 Materials Difficult to Subsample: Nutritional Studies

LSNAA is extremely useful in the determination of major, minor, and trace elements in foodstuff, as large samples can be analyzed without resorting to subsampling. In fact, comparison of the results obtained from subsamples of varying mass gave an indication that a sample of 1 kg of wheat is more representative than small samples in the range of 40–1000 mg.\(^\text{57}\) It is also feasible to determine trace elements in liquid diets, e.g., juices and milk, by LSNAA.

8.4 Valuable Material of Irregular Shape

Subsampling of archaeological and cultural heritage objects is generally prohibited, as these objects have to be preserved intact. LSNAA has the capability for nondestructive bulk analysis of the whole object. In comparison, other established nondestructive analytical methods, such as XRF or analytical techniques based on charged particle irradiation (PIXE, particle induced X-ray emission, IBA, ion beam analysis), can only analyze superficial layers of the sample and provide limited information over the whole volume of the object of interest.\(^\text{58,59}\)

The particular advantage of INAA being noninvasive and a true multielemental technique is combined in LSNAA with the ability to analyze bulky objects as a whole, without any visual damage to the valuable cultural heritage objects. Art historians, conservators, and museum staff do not generally allow damaging such valuable objects by removing a portion for analytical purposes. However, sometimes only the elemental composition can decisively distinguish whether an object is different from what it appears to be from visual inspection.

8.5 Other Applications

Direct analysis of large samples provides a unique opportunity for (the validation of) (sub)sampling studies.

Activity Determination and Localization of Radioactive Point Source in a Large Medium

Zeev B. Alfassi
Ben Gurion University, Beer Sheva, Israel Universit`a degli Studi and INFN of Milano, Segrate

1 INTRODUCTION

Many measurements of radioactivity involve counting of γ rays or neutrons emitted by bulky samples, which are referred to as a box. While it is simple experimentally in the case of a point source in a known position, to transform the measurements of count-rate to activity (disintegration per unit time) and hence to the number of radioactive atoms, the problem can be the inaccuracy in the case of a small source in an unknown position in a bulky medium.

The inaccuracy is because of two factors: (i) the self-absorption and scattering of the photons in the sample and (ii) the unknown solid angle in which the detector sees the point source. Thus, in the case of a radioactive small source in an unknown position in a large box, we need to find its position in order to transform the count-rate to activity (see Instrumental Neutron Activation Analysis).

The measurements are different if the source is emitting γ rays or neutrons. In the case of the γ-emitting source, measurements can be done only for the photons that do not interact with the media surrounding the source, except for the media of the detector, by measuring the full-energy peak. In the case of neutron emission, the measurement of the spectrum of the emission is more difficult. In addition, most of the emitted neutrons are fast neutrons, while most of the detectors are more sensitive to thermal neutrons; hence, for better statistics, the neutrons are measured after their interaction with the surrounding material.

The localization of the source can be done only by measurement with more than one detector. The simple case is when it is known that the source in on a given line. In this case, there are only two unknowns: the activity and the location on the line; and two detectors on parallel faces of the box, collinear with the source, are sufficient. However, in the general case, there are four unknowns: activity and the three coordinates in space; then, at least four detectors are needed.

2 γ-EMITTING SOURCE

2.1 Two Collinear Detectors

2.1.1 Nonabsorbing Media

Two factors cause the decrease in efficiency with the increase in distance from the detector: (i) the isotropic propagation of γ rays, which leads to a smaller solid angle in which the detector sees the source with the increasing distance, i.e. the 1/distance² law and (ii) the absorption of γ rays inside the sample, i.e. the exp(−µ· distance) law. In order to separate these factors and dealing with only the first factor, a relative nonabsorbing media should be used. This can be done either with a low dense sample or, in the case of a low value of µ, the linear absorption coefficient, with high-energy γ rays.¹

The mathematical treatment uses the assumption of the “virtual point detector” model for the voluminous γ detectors.²⁻⁹ The bulky detector is treated as a virtual point detector on the symmetry axis of the detector at a distance d from the cap. This means that the count-rate in the absence of an absorbing/scattering medium due to a radioactive source at a distance y from the detector cap C(y) is given by the equation C(y) = C(y = 0)· d², where d is...
the distance from the detector cap to the virtual detector point, \( y \) is the distance from the source to the detector cap, and \( C(0) \) is the count-rate measured on the detector cap.

The localization of the radioactive point source is done by two detectors on parallel faces of the box, collinear with the source, as shown in Figure 1. In Figure 1, \( d_{1j} \) is the distance between the inner face of the box and the detector \( j \) cap and \( d_{2j} \) is the distance between the detector cap and its effective virtual point detector; thus, if \( d_j = d_{1j} + d_{2j} \), we get the equation for the count-rate because of a source at a distance \( y \) from the inner face of the box.

\[
C_j(y) = \frac{C_j(0) \cdot d_j^2}{(y + d_j)^2} \quad j = 1, 2
\]  

For a point source at the center of a box with a linear dimension \( 2a \) (on the line of centers), this equation leads to

\[
C_j(\text{center}) = \frac{C_j(0) \cdot d_j^2}{(a + d_j)^2} \quad j = 1, 2
\]  

For a point source located at a distance \( x \) from the center, the distances from the box faces are \( a + x \) and \( a - x \), and hence Equation (2) yields

\[
C_1(y) = \frac{C_1(0) \cdot d_1^2}{(a + x + d_1)^2}; \quad C_2(y) = \frac{C_2(0) \cdot d_2^2}{(a - x + d_2)^2}
\]  

The normalized count-rate (normalized to the count-rate at the center of the box) \( N_1(x) \) and \( N_2(x) \) are

\[
N_1(x) = \frac{(a + d_1)^2}{(a + x + d_1)^2}; \quad N_2(x) = \frac{(a + d_2)^2}{(a - x + d_2)^2}
\]  

Since both detectors are quite similar, we can accurately approximate \( d_1 = d_2 \). Equation (4) shows that, if we take the square roots of the reciprocal count-rate, the denominators are the same, while in the numerators, \( x \) appears once with a plus sign and once with a minus sign, which means that adding them cancels the terms with \( x \):

\[
\frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}} = 2
\]  

This sum has the units \( s^{0.5} \cdot \text{count}^{-0.5} \) and hence the square of its reciprocal value has the units counts per second, which are the units of count-rate. The definition of a new mean according to this equation, the harmonic mean of the square roots, leads to a mean that is independent of the position of the source.

\[
M_{SH} = \left( \frac{\frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}}}{2} \right)^2 \Rightarrow M_{SH} = \frac{4}{\left( \frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}} \right)^2}
\]  

Equation (5) indicates that \( M_{SH} \), defined for the normalized counts, should be equal to 1, independent of \( x \). It was found experimentally\(^{1}\) that the deviation of \( M_{SH} \) from 1 is always below 10\% and, in most cases, not more than 2–3\%.

This constancy of \( M_{SH} \) indicates the method of measuring the activity of a point source accurately within a box without having to know the position of the source. As we do not know the counts with the source at the center of the box, \( M_{SH} \) is not calculated with the normalized countrates, but with the experimental ones. In this way, \( M_{SH} \) is independent of the position of the source, but dependent proportionally on the activity of the source. The box is calibrated for its efficiency by a standard point source with known activity, which is denoted by \( \text{Act(Std)} \), positioned anywhere on the line of the centers. Let us assign its mean square harmonic \( M_{SH} \) by \( M_{SH}(\text{Std}) \). The activity of any unknown source \( \text{Act(u)} \) of the same energy, positioned

---

**Figure 1** The dual detectors measuring system.
somewhere (unknown) on the line of centers, is given by

\[ \text{Act}(a) = \frac{M_{\text{SH}}(u)}{M_{\text{SH}}(\text{Std})} \cdot \text{Act(Std)} \quad (7) \]

\( M_{\text{SH}} \) is calculated from the count-rates of the two detectors (Equation 6). As the unknown source cannot be removed for the measurement of the standard source, the counts due to the standard source for each detector are calculated by the subtraction of two counts; one with the unknown source alone and the other with both of the two, the unknown source and the standard one.

If the exact place of the source in the box is required, the position of the source can be found from the ratio of the count-rates of the two detectors. From Equation (5):

\[ R = \sqrt{\frac{N_1}{N_2}} = \frac{(d + a) + x}{(d + a) - x} \quad (8) \]

and hence

\[ x = (d + a) \cdot \frac{1 - R}{1 + R} \quad (9) \]

where \( x \) is the distance from the center of the box toward detector 2. Care should be taken to include \( d \), the distance of the virtual point detector from the detector cap (which depends on the \( \gamma \)-ray energy) and also the thickness of the box and the distance of the outer face of the box from the detector cap.

2.1.1.1 Calculated Error for Longitudinal Sources

The calculation till now assumes that the source is a very small one, close to a point. In the following, we calculate the error induced by a longitudinal source of length \( 2b \) lying on the line of centers with its midpoint coinciding with the midpoint of the line of centers (Figure 2).

The activity of an infinitesimal piece of the source with length \( dx \) is \( A \cdot dx/2b \), where \( A \) is the total activity of the source. The normalized count-rates of the longitudinal source–detector (normalized to the whole activity being concentrated in the center) is given by the following integral

\[ N = \frac{\frac{A}{2b} \int_0^{2b} dx/(d + a - b + x)^2}{A/d + a} \]

By integration, the normalized count-rates are

\[ N = \frac{(d + a)^2}{(d + a)^2 - b^2} = \frac{1}{1 - [b/(d + a)]^2} \quad (10) \]

If \( b/(d + a) \ll 1 \), \( N \) can be approximated as \( N = 2b/(d + a) \); this is the fractional error because the source is not a point source. As long as \( b/(d + a) < 0.3 \), the error due to a longitudinal source (Equation 10) is less than 10%.

2.1.2 Absorbing Media – Parallel \( \gamma \) Lines

2.1.2.1 Activity Calculation

The use of collimated detectors to measure only parallel photons, as, for example, in a medical double-headed \( \gamma \) camera, eliminates the decrease in the solid angle in which the detector sees the source with the increase in the source–detector distance and leaves the effect of the source–detector distance to the sole effect of absorption/scattering.\(^{10}\) In this case, the geometric mean of the count-rate of the two detectors can be used to calculate the activity of the unknown source:

\[ C_1 = C_{10} \cdot e^{-\mu(a-x)}; \quad C_2 = C_{20} \cdot e^{-\mu(a+x)} \quad (11) \]

From Equation (11), the geometric mean of the two count-rates measured by the two detectors is given by

\[ M_G(x) = \sqrt{C_1(x) \cdot C_2(x)} = \sqrt{C_{10} \cdot C_{20} \cdot e^{-2\mu a}} = e^{-\mu a} \sqrt{C_{10} \cdot C_{20}} \quad (12) \]

Equation (12) shows that the geometric mean of the two count-rates is independent of the position of the point source but depends linearly on the activity of the source. Thus, the geometric mean can be used to measure the activity of an unknown source using a calibrated source positioned on one of the faces of the box between the detector and the box:

\[ \text{Act}(a) = \frac{M_G(u)}{M_G(\text{Std})} \cdot \text{Act(Std)} \quad (13) \]

2.1.2.2 The Error due to a Longitudinal Source

The mathematical approach described previously assumed that the active source is very thin. In the following, the error is induced if the source has a dimension in the plane of the detectors. Let us assume that the whole activity is spread over a length \( b \) (Figure 2). Then, the count-rates due to infinitesimal length \( dx \), assuming there is no absorption by the medium, are \( \frac{G_0}{b} dx \) and \( \frac{G_0}{b} dx \). The
count-rates due to the absorption effects are (Figure 3):

\[ C_1 = \frac{C_{01}}{b} \int_0^b e^{-\mu(x+d)} dx = \frac{C_{01}}{\mu b} e^{-\mu d} \cdot (1 - e^{-\mu b}) \]

\[ C_2 = \frac{C_{02}}{b} \int_0^b e^{-\mu[2(x-d)]} dx = \frac{C_{02}}{\mu b} \cdot e^{-\mu 2a} \cdot e^{\mu d} (e^{\mu b} - 1) \]

where 2a is thickness of the box, d is the distance of one side of the source from one of the detectors, and x is the distance of the infinitesimal length dx from the same side of the source. The geometric mean is

\[ M_G = \sqrt{C_1 \cdot C_2} = e^{-\mu a} \sqrt{C_{01} \cdot C_{02}} \frac{(1 - e^{-\mu b})(e^{\mu b} - 1)}{\mu b} \]

The correction factor K due to the dimension b perpendicular to the detector’s plane is given by

\[ K = \frac{\sqrt{(1 - e^{-\mu b})(e^{\mu b} - 1)}}{\mu b} \Rightarrow K = \frac{e^{\mu b/2}(1 - e^{-\mu b})}{\mu b} \]

As long as \( \mu b < 1.5 \), the error is <10% (\( K < 1.10 \)). For example, for \(^{99m}\)Tc in water \( \mu = 0.152 \text{ cm}^{-1} \), then for an object with size <10 cm, the error is <10%.

### 2.1.3 The General Case

The general case is where both, the solid angle in which the detector sees the source and the absorption/scattering, are operational.

#### 2.1.3.1 Activity Calculation

In the previous sections, it was shown that, when only the solid angle is important, the activity can be calculated from the square root harmonic average, while when only absorption is operational the geometric average is the right method to calculate the activity. Since these two effects are independent, it can be expected that, in the general case, the right answer is a weighted product of these two averages. The weighing must ensure that the units of the new average are the same as count-rate(\(^{10}\)):

\[ M_{GSH} = M_{SH}^a \cdot M_G^{1-a} \]

It was found that \( \alpha \) depends on the contents of the box(\(^{10}\)) and \( \alpha \) can be found from the measurement of the count-rates at several points of the box. However, for an unknown box, this means opening the box or reproducing a similar box for calculating \( \alpha \). The method to measure the radioactivity in the box without the need to open it is by previous localization of the radioactive point source, as discussed in the next paragraph.

#### 2.1.3.2 Localization of the Point Source

It was shown(\(^{11}\)) that the count-rate of a detector positioned on the face of a box as a function of the distance of a point source, positioned inside the box filled with polypropylene, from the detector is close to exponential dependence, but is not very accurate. The exponential dependence on the distance from the box’s face is improved if, instead of taking the count-rate of one detector, the ratio of the count-rates of two detectors positioned on parallel faces is taken. Another possibility to improve the exponential dependence is to position the detector at a distance from the face of the box. However, increasing the distance between the detector and the box leads to worse statistics because of a smaller count-rate. In addition, the use of the ratio of the count-rates of two detectors is preferable as the equation of the count-rate \( C(x) \) versus the distance of the source from the box face \(-x\),

\[ C(x) = C(0) \cdot e^{-\mu x} \]

has two parameters, \( C(0) \) and \( \mu \), which require at least two calibration experiments. Performing two calibration measurements is difficult if we do not want to open the box. On the other hand, if the two detectors are equal, or made to be equal, by adding a factor to one of them,
the two parameters of the equation of the ratio of the count-rates
\[ R(x) = R(0) \cdot e^{-\mu \cdot x} \] (21)
can be shown to be correlated, leading to only one parameter.

If the length of the box is \( a \), then \( R(0) \) and \( R(a) \) are reciprocal numbers, as changing from 0 to \( a \) means replacing the detectors. Substituting \( R(a) = 1/R(0) \) yields
\[ R(0) = e^{\mu \cdot a/2} \] (22)
Hence
\[ x = -\frac{a}{2} \left( 1 - \frac{\ln[R(x)]}{\ln[R(0)]} \right) \] (23)

The activity of the source cannot be calculated from the ratio of the count-rates as \( R(x) \) is independent of the source activity. For the determination of the source activity, the measurement of the count-rate of one detector must be used, together with the calculated \( x \) from Equation (23). Since in the case of the detectors close to the box, the dependence of the count-rate on the distance \( x \) is quite complex, it is preferable to use measurements at a distance between the detectors and the box. As mentioned before, there are two unknowns, \( C(0) \) and \( \mu \), but \( \mu \) for one detector measurement can also be deduced from the measurements of the ratio of the count-rates at the same distance detector box. It was shown earlier that \( \mu \) for the expression \( R(x) \) can be found from \( R(0) \) and the box length. The \( \mu \) for one detector count-rate was proven to be one-half of the \( \mu \) for the ratio of the count-rates.\(^{11}\)

### 2.2 Four Detectors

Old lung counters were made of two large-sized phoswich detectors. In order to increase the resolution of modern lung counters, semi-planar Ge detectors were used. Owing to the small size of the available Ge detectors, 3 or 4 detectors were typically used to cover the area of the two lungs previously covered by two phoswich detectors.\(^{12,13}\) A commercially available set of four detectors is the Lung-Counter composed of four semiplanar HPGe detectors that were positioned two on each lung on the chest.

#### 2.2.1 Lung Detector

The basic assumption generally made when calibrating a lung counter is that the deposition of the radioactive aerosols in lungs is homogenous; however, it has been reported that the distribution is a function of the aerosol size and the breathing rate and changes with time.\(^{14}\) In some cases, the contamination can be present in the form of a single “hot” particle. The count-rate of an external detector is strongly dependent on the position of the “hot particle”; the possible errors in activity determination due to deviations from homogeneity were evaluated to be factors of 26, 3, and 1.8 for photon energies of 17, 60, and 1000 keV respectively,\(^{15}\) and factors of up to 20 were measured for natural uranium.\(^{16}\) The extra information due to more than one detector allows the localization of a point source in the lungs.

#### 2.2.1.1 The Mathematical Method

The mathematical method used is applicable not only for localization of radioactive sources but also for any technique using several measurements to identify an unknown.\(^{17}\) The most well known analysis using this mathematical method is the identification of an analyte from its electron-impact mass spectrum (EIMS).\(^{18}\) but the method can be also used for source identification.\(^{19–21}\) It is based on a calibration with a radioactive point source positioned consecutively in various locations in a phantom, which is the actual bulky material. For every positioning, the four detectors measure the pulse height spectra, and the count-rate for each \( \gamma \) full-energy peak is then calculated. The position of an unknown radioactive point source can be found by comparing its count-rates measured by the four detectors with similar data obtained for each of the various locations during the calibration. The mathematical problem is to find which of the sets of the standards (which, in our case, contain the results of the four detectors) best fits the four count-rates of the unknown.

The values of the count-rates of the four detectors are set as the components of a vector and all the vectors are normalized to unity length.\(^{22}\) Each normalized vector can be seen as a single point on a hypersphere with a unity radius in an \( n \)-dimensional hyperspace, where \( n \) is the number of the vector components (the number of the detectors). If two vectors (points on the \( n \)-dimensional hypersphere) are identical in all the components, there will be a perfect “match” that represents the same point in the hyperspace. However, because of instrumental instability and the statistical nature of the measurements, the point of an unknown coincides exactly with one of the points in the library of standards only rarely. Actually, even repeating the same measurement at the same point rarely gives exactly the same count-rates. The problem of finding the best match for the vector of an unknown in the library of the vectors of standards can be solved in principle by two methods (two matching factors). The first method can be described as the “nearest-neighbor” technique, while the second can be defined as the “minimal contact angle”, although, in many cases, it is called the dot product method after the mathematical operation used to calculate the angle.
NUCLEAR METHODS

The first method calculates the distances between the head of the vector of the unknown and the heads of each of the vectors of the standards (the library), looking for the minimum distance, i.e. the minimum of

$$\Delta_j = \sum_{i=1}^{n} (u_i - s_{i,j})^2$$

(24)

where $u_i$ is the $i$th component (the detector $i$) of the vector of the count-rates of the unknown and $s_{i,j}$ represents the $i$th component of the $j$th vector in the library of standards. The summation is performed over all the components of the vector (all the detectors). It should be emphasized that all the vectors must be normalized (to be of unity length) in order to compensate for different activities of the standard and the unknown:

$$u_i = \frac{U_i}{\sum_{k=1}^{n} U_k}; \quad s_{i,j} = \frac{S_{i,j}}{\sum_{k=1}^{n} S_{k,j}}$$

(25)

where $U$ and $S$ are the original un-normalized vectors.

In the second method, the angles between the unknown vector and each of the standard vectors are calculated. The cosine of the angle between two vectors can be calculated from the values of their components by using the scalar “dot product”:

$$\cos \theta_j = \frac{s_j \cdot u}{|s_j| \cdot |u|} = \frac{\sum_{i=1}^{n} s_{i,j} \cdot u_i}{\sqrt{\sum_{i=1}^{n} s_{i,j}^2 \cdot \sum_{i=1}^{n} u_i^2}}$$

(26)

The summation is done over all the components of the two vectors (which are of the same dimension). Actually, the calculation of the angle does not require the normalization of the vectors and can be performed on the original data:

$$\cos \theta_j = \frac{S_j \cdot U}{|S_j| \cdot |U|} = \frac{\sum_{i=1}^{n} S_{i,j} \cdot U_i}{\sqrt{\sum_{i=1}^{n} S_{i,j}^2 \cdot \sum_{i=1}^{n} U_i^2}}$$

(27)

However, it is preferable to use the normalized vectors at least for all the standards. Even if the vectors are not normalized explicitly, normalization is still performed in the process of calculating the lengths of the vectors in the denominator of Equation (27), which includes division by the lengths of the vectors. It is better to calculate the lengths only once in the normalization process rather than to calculate them for each unknown.

Figure 3 The realistic phantom used in the experiments.

The Experimental System

The measurements were performed by the NRC-Negev lung counter system, which consists of four semiplanar HPGe detectors measuring a uranium source inside a phantom, as can be seen in Figure 3. The information from each detector was analyzed separately by a multichannel analyzer. The uranium source was a sealed cylinder with a radius of 1.5 mm and length of 5 mm, which contained natural uranium (99.27% $^{238}$U and 0.72% $^{235}$U) with an activity of 1.85 kBq. The main $\gamma$ lines were 92 keV because of the $^{238}$U chain (due to $^{234}$Th) and 186 keV mainly because of $^{235}$U. The quantitative information from each measurement was the count-rates of the 186 and 92 keV peaks (the areas under the peaks divided by the counting time). Other $\gamma$ peaks were also observed; however, their counts were smaller, implying larger statistical errors, and they were not used in the analysis.

The detectors were calibrated using a realistic phantom designed by Lawrence Livermore National Laboratory. The phantom lungs used were made of tissue-equivalent plastic material and had 28 cylindrical holes, where point sources of natural uranium could be placed, as can be seen in Figure 4. All holes were normally filled with cylinders made of the same tissue-equivalent plastic as the lungs, and a small portion of the cylindrical filling was replaced by the source only at the checked position, so that the absorbing properties of the lungs remained practically unchanged and fully simulated the human lungs. The 56 points for placing the sources at different locations (two points in each hole) were distributed all over the lungs. Twenty-eight points were located on the upper surface of the lungs and 28 on the lower surface.
The matching factors ($\Delta_j$ and $\cos \theta_j$) of the counts for the source placed at an unknown position with each of the 56 different points of the library data base were calculated. On the basis of the minimum value of $\Delta_j$, the matching factor, or a maximum of $\cos \theta_j$, the other matching factor, a “predicted point” was determined and compared with the actual point location. If there was a match between them, it was called a success or just a hit.

The difference between the calculated and the actual activity (the error in calculation of the activity) was calculated as follows. After determination of the actual activity (the error in calculation of the activity) was calculated from the count-rates of the source at the unknown position, and the efficiency factor for the guessed (calculated) source was calculated as follows. After determination of the actual activity (the error in calculation of the activity) was calculated from the count-rates of the source at the unknown position, and the efficiency factor for the guessed point was determined. The difference between this calculated activity for each single measurement and the known source activity was the error for the specific measurement.

There was a one-to-one correlation between $\cos \theta$ ($\theta$ stands for the angle between the two vectors) and the distance between the points (heads of the vectors) in the hyperspace, and it was found, in the case of localization of a radioactive point source in the lung phantom, that Equations (3) and (5) actually gave the same results.\(^{(19)}\)

The Use of Weighted Results  Stein\(^{(2)}\) found that the identification in EIMS gets better if, instead of raw ion intensities, the values (ion intensity · ion mass)\(^{1/2}\) are taken as the components of the vectors. This choice of components of the vectors increases the weights of low-intensity peaks produced by ions of big masses.

In our case of the lung phantom, it was also found that the number of “hits” increased slightly if raw values of the count-rates were multiplied by weighing factors. The various weighing factors studied are given in Table 1. For calculation of the least distance, it was found that the best results were obtained for weights taken as the reciprocal of the mean of the normalized count-rates of the unknown and the library vectors. The raw vectors are first normalized, and the weights are calculated from the normalized vectors. In a mathematical notation, this means that, instead of searching for the library vector $L$ that leads to the minimal values of $\sqrt{\sum_{i=1}^{n}(U_i - U_j)^2}$ for the various vectors of the library (where $U$ is the vector of the unknown), we are looking for the vector $L$ that yields a minimal value of $\sum_{i=1}^{n} (U_i - L_j)^2/(U_i + L_j)$. Because we are looking for the minimal distance, this assigns bigger weights to the measurements of larger counts with smaller statistical errors. When these weights are used, the fraction of the “hits” (where “hit” means that the method detects the correct location of the source) increases from 78 to 82%\(^{(19)}\). Although there were only 82% of “hits”, the mean error in the calculated activity was only 10.4% because, in the “nonhit” cases, the resulted position was

</table>

quite close to the real one, which led to a relatively small error in the calculated activity.

Homogenous versus Point-wise Distribution  Application of this method to a homogenously distributed source in the lungs of the phantom results in the best “fit” for one of the points in the center. The error in the activity is quite large in this case, almost 40%. It seems that this method can work only when applied to inhomogenously distributed radioactive contaminants. However, this problem can be solved by adding another vector to the set of the standards. This vector is the response of the four detectors to a phantom with homogenously distributed radionuclides, which can be defined as a “virtual point”. Another possibility for a vector representing the homogenously distributed lungs is to take the arithmetic mean of the 56 calibrating points for each one of the four detectors. With this extended set of standards, the “guessed point” for homogenously distributed lungs is taken to have the same mean activity as the center of the virtual vector. The error in the calculated activity is below 5%. Thus, one can actually distinguish between a homogenous distribution and a point location.

Simultaneous use of two γ lines  In the case of uranium contamination, the count-rates of two relatively strong γ lines were measured by the four detectors, namely, the lines at 92 and 186 keV. The 92-keV line is due to a daughter in the $^{238}$U chain, while the 186 keV line originates mainly from $^{235}$U. These γ lines, when used separately, provide approximately the same fraction of “hits” and the same mean error in the activity, but a closer observation shows that the cases of “nonhits” are not the same for both the lines. This is reasonable because the main cause for a “miss” is the statistical nature of the count-rates. It was found that analyzing the two energy peaks together could provide better results. Eight-component vectors were composed. Out of these, four components were the 92 keV count-rates measured by the four detectors, while the other four components were count-rates measured by the same detectors for the 186 keV line. The normalization of the vectors involved all the eight components. It can be seen in Table 2 that the fraction of “hits” increased from 82%, when each of the energies was analyzed separately, to 94%, when the two energies were analyzed together using an eight-dimensional vector. The mean error in the activity decreased from 10.4 to 3.8%.

Table 2 gives the percentage of “hits” and the error in the calculated activity for four detectors, both for using only the count-rates at either the 186 or the 92 keV peak (vectors of four dimensions) and the simultaneous count-rates at the 92 and the 186 keV peaks (eight-dimensional vectors). In the case of Table 2, the library was built from all the 224 experiments, and each standard vector was the average of four repeated experiments. The unknown vector was one of the 224 vectors, leading to the same vectors being used as part of the library, although in an average with three other experiments and as the unknown. In Table 3, the same results are given when the average of only two repeating experiments (112 measurements) was used to calculate the library, while
the other 112 measurements were treated as unknowns. There are six possibilities ($C_2^6$) to choose the two repeating experiments used for the library; the results in Table 3 are the average of these six possibilities.

However, using the two $\gamma$ lines presents a problem when the isotopic composition of the uranium in the calibration standards is different from that of the unknown, because the two lines are produced by different isotopes. It was shown that, if the isotopic compositions were different, errors in localizing a source and determining its activity were larger with the eight-dimensional vector than with the four-dimensional one. This study shows that, in such a case, the method of simultaneous analysis of two $\gamma$ energy peaks leading to eight-dimensional vectors can still be used to improve the accuracy, but the eight-dimensional vectors should be normalized in an unusual way, which can be called double half-normalization. In this method, the four count-rates of each $\gamma$ energy are normalized separately. The components of the normalized vector $c_j$ are

$$c_j = \frac{C_{92,j}}{4}; \quad \text{for } j = 1-4$$

$$c_j = \frac{C_{186,j-4}}{4}; \quad \text{for } j = 5-8$$

In the expressions above, the measured count-rates are $C_{92,j}$ and $C_{186,j}$, where $j = 1-4$ represent the four different detectors. Pelled found that this complex normalization (the lengths of the vectors are actually 2) decreases the fraction of “hits” in the case of the same isotopic composition only from 94 to 93%, which is still much higher than the success rate when a single $\gamma$ line is used. When the isotopic compositions are different, this larger dimensionality increases the fraction of “hits” almost to the same degree as in the case of the same isotopic composition. However, when the isotopic compositions are extremely different, the statistics of one of the energy lines is expected to be poor; therefore, it is better to use only the most abundant $\gamma$ line.

**Detectors at the Back** Another way to increase the dimensionality of the vectors is to use more detectors. In practice, the four detectors cover most of the area of the lungs, and, physically, there is no place for additional ones. However, they can be mounted on the back of the phantom. Counts by detectors mounted on the back are usually lower due to stronger absorption of the photons. Hence, longer counting times are required to get good statistics. Count-rates for the normal counting time with the detectors positioned at the back of the phantom were studied, thus simulating an array of eight detectors. The results can be represented by eight-dimensional vectors or 16-dimensional vectors if both the $\gamma$ energies (92 and 186 keV) are used. The percentage of “hits” exceeded 99%, suggesting that placing lung detectors behind the phantom, by mounting them in a chair support, is worthwhile. There is actually no need for eight detectors as only two additional detectors at the back increase the fraction of “hits” to about 99%.

</table>

Possibly more interesting results of this study are that, even when only four detectors are used, it is considerably better to locate one or two of them at the back. \(^{241}\) Tables 4 and 5 yield the percentage of “hits” and the error of the calculated activity both for using the 186 keV peak alone and for the simultaneous use of the 92 and 186 keV peaks. Each line gives the results for another arrangement of the four detectors. The detectors in the front are assigned by A, B, C, and D, while the detectors at the back are denoted by BA, BB, BC, and BD. Detector A is located opposite the upper part of the right lung. Detector B is located opposite the upper part of the left lung. Detector C is located opposite the lower part of the left lung, and detector D is located opposite the lower part of the right lung. When measuring very low energy $\gamma$ photons, as, for example, when measuring contamination with $^{239}\text{Pu}$, the detectors at the back hardly see anything. However, Tables 4 and 5, in which each line giving a different arrangement of the four detectors shows that, even for natural uranium, with not very high energy photons, positioning of one or two, out of the four, detectors at the back leads to considerably more accurate results. This is clearer in the case of only one photon energy or if the library used were counted for a relatively short time (6 h in Table 5 compared to 12 h in Table 4).

3 NEUTRON SOURCES

The main difference between neutron sources and $\gamma$ sources is that, while $\gamma$ sources emit photons of discrete energies, mainly one or two major lines, the radionuclidic neutron source, both fission sources or ($\alpha, n$) sources, emits a spectrum of neutrons, mainly fast ones with an average of more than 1 MeV. Another difference is that it is quite easy to measure the spectrum of the $\gamma$ photons emitted from the box, and the resolution of the energy spectrum is quite high, while, on the other hand, measurement of the spectrum of the neutrons is quite a task, and the resolution of the energy spectrum is quite low. Taking these two differences and the much larger sensitivity of usual neutron detectors to thermal neutrons than to more energetic neutrons, it is almost impossible to measure only neutrons that reach the detectors without interaction with the box and the surrounding materials, as was done for $\gamma$ photons. Not only the interaction with the box but also the interaction with the shield of the experimental system should be considered, as the detectors must be shielded from outside radiation and the researcher must be protected from the neutron irradiation. This shield, if made from hydrogen-containing material, not only shields the detector from outside
It was found that, when two $^3$He detectors were positioned on two parallel faces of a box with a small neutron source in the box on the line connecting the two detectors, the ratio of the two count-rates was an exponential function of the distance between the source and one of these faces. The exponential dependence was found to be independent of the medium in the box, from air to highly hydrogenated material, although the coefficient of the exponentiality depended on the medium. This is the same as that described earlier for two $\gamma$ detectors in the general case and hence the same equation should apply:

$$x = \frac{a}{2} \left( 1 - \frac{\ln[R(x)]}{\ln[R(0)]} \right)$$  \hspace{1cm} (29)

where $x$ is the distance from the box’s face, $a$ is the length of the box (the distance between the two faces on which the detectors are positioned), and $R$ is the measured ratio of the two count-rates. $R(x)$ is the ratio for the unknown source and $R(0)$ is the ratio for an external source positioned on the face of the box ($x = 0$). It was found that Equation (29) yields quite accurate results, as can be seen in Table 6. In this table, $\Delta x/a$ is the fractional error in the location. As can be seen in this table, the calculated location is quite accurate except for the cases where the source is positioned very close to one of the two faces of the box. This is probably due to thermal neutrons coming to the close detector only by scattering from the shielding, as the neutrons coming directly from the source are too energetic to react with the $^3$He in the detector. In order to get more accurate results, 5-cm polypropylene slabs were positioned between the detectors and the box.\(^{(26,27)}\)

### 3.2 More than Two Detectors

When the unknown neutron source is not on the line (actually a plane as the detectors are quite long) connecting the two detectors, it is found that Equation (29) gives the correct result only if $R(0)$ is measured for the external source positioned on the face of the box in a plane parallel to the detectors’ plane but passes through the unknown source. Therefore, now the problem is to find this plane. Two solutions are found to this problem. In the first solution, three pairs of $^3$He detectors were positioned...

detectors are positioned on two parallel faces of the box.\(^{27,28}\) It is found that the pair that gives the highest geometric mean of the count-rates is the closest to the unknown source and hence the external source should be positioned in this plane. However, this still gives an error of one-sixth of the width of the box and, consequently, for larger boxes it will require more detectors. A better solution that requires only four detectors involves the moving of the external source on different faces by an iterative method.\(^{29}\)

The iterative method was applied to localize the unknown neutron source by finding successive approximations to the solution, starting from an initial estimate regarding the unknown source plane (y coordinate). First, the $x$ coordinate of the unknown source was calculated, using Equation (29), from the results of the two detectors on the $y$ axis (detectors 1 and 2, which are on parallel faces of the box, as can be seen in Figure 5). Both $R(x)$ and $R(0)$ were measured by detectors 1 and 2. Measurements were made of the unknown source alone and together with a known (calibrating) source placed outside the box; $R(0)$ was the difference between the two measurements. In this first step, $R(0)$ was measured with the known

### Average

- **Table 7**: The iteration calculations of the source-to-detector distance (cm) for row b of the experimental results.
- **Table 8**: Pre- and postiteration distance calculations between the real source position and the calculated one.
performed after the initially estimated calculation of experimental results. For most points, two iterations were done by iterations. Table 7 presents, as an example, √ accuracy.

estimate already yielded a major improvement to the (two consecutive calculations of √ was the same as in the previous iteration. Table 7 shows the various calculations of √ and was used to calculate the y coordinate, according to Equation 29, using R(x), also from detectors 3 and 4. Then, the calibrating source was moved to the y axis at the calculated y (as close as possible to the calculated y cell). R(0), was measured again and a new value of x was calculated. This process was repeated until either x or y was the same as in the previous iteration.

Table 7 shows the various calculations of x and y done by iterations. Table 7 presents, as an example, the iteration calculations of row b (Figure 5) of the experimental results. For most points, two iterations were performed after the initially estimated calculation of x, until x or y recurred. It was found that one iteration (two consecutive calculations of y and x) after the initial estimate already yielded a major improvement to the accuracy.

Table 8 shows the distance between the real source position and the calculated one, √[(ycalcd - yreal)² + (xcalcd - xreal)²] both for x and y calculated with central R(0) for both coordinates and the distances calculated after completing all the iterations. One to four iterations are required, depending on the source's position. Iteration calculations reduce the average calculated distance between the real source position and the calculated one from 2.46 to 1 cm and reduce the maximal distance from above 10 to <4 cm.

Charged particle activation analysis (CPAA) is an analytical method for elemental analysis. It is based on charged particle (CP) induced nuclear reactions producing radionuclides, that are identified and quantified by their characteristic decay radiation. CPAA allows trace element determination in the bulk of a solid sample, as well as characterization of a thin surface layer, i.e. determination of mass thickness or composition.

Advantages of CPAA are: (1) good precision, (2) low detection limit, (3) outstanding accuracy, (4) absolute, i.e. reference method, (5) independent, i.e. based on a totally different principle than more common methods for elemental analysis (atomic/optical emission and mass spectrometry), and hence not subject to the same systematic errors, (6) traceability, (7) not subject to surface contamination for trace element determination in the bulk, (8) if instrumental analysis is not possible it is not subject to reagent blank errors, and (9) errors due to nonquantitative yield (and even nonreproducible yield) can be corrected for. Disadvantages of CPAA are its inherent complexity and costs, it is not suitable for liquid samples, and heating occurs during irradiation. Speciation, depth profiling, or scanning is not possible.

This article covers (1) the principles on the slowing down of CPs in matter, nuclear reactions, and interferences; (2) experimental details concerning irradiation and activity measurement; (3) conceptual and experimental procedures and data handling, from the problem to the final result; (4) perspectives. References to relevant databases are
made. A systematic overview of all possible CPAA applications is beyond the scope of this article.

1 INTRODUCTION

CPAA is an analytical method for elemental analysis. Speciation (i.e. discrimination between different oxidation states of the analyte element or between different compounds) is not possible. CPAA is based on CP induced nuclear reactions producing radionuclides and their characteristic decay radiation is measured. The radionuclide is identified by measuring its energy and/or half-life, i.e. qualitative analysis. Quantitative analysis is performed by measuring the number of particles or photons emitted, i.e. radioactivity.

CPAA provides a good precision, low detection limits, and accuracy. It can be considered as an absolute (reference) and an independent method for elemental analysis of solid samples. There is no need for standards that are comparable to the samples, or for standards where the analyte content is determined by another analytical method. Traceability conditions are fulfilled, except for the stopping power correction. CPAA is based on a totally different principle than more common methods for elemental analysis (e.g. atomic or optical emission and mass spectrometry), and hence it is not subject to the same systematic errors. It is not subjected at all to errors related to dissolution of the sample and chemical separation (e.g. preconcentration). If instrumental analysis is not possible, then radiochemical CPAA can be applied. Errors due to reagent blanks do not exist. Errors due to surface contamination (e.g. determination of bulk oxygen in aluminum) can be avoided easily. Finally, errors due to nonquantitative yield, and even nonreproducible yield, can be corrected for.

CPAA can be applied for trace element determinations as well as for characterization of thin surface layers. It has proven its outstanding capabilities for the determination of trace light elements (boron, carbon, nitrogen, and oxygen) in the bulk of high purity metals and semiconductors. Recently, CPAA has been applied for the characterization of surface layers, such as the determination of mass thickness or composition (stoichiometry). The disadvantages of CPAA are its inherent complexity and cost, it is not suitable for liquid samples, and heating occurs during irradiation. Neither depth profiling nor scanning is possible for surface characterization.

2 INTERACTION OF CHARGED PARTICLES WITH MATTER

Most CPs do not induce nuclear reactions and are slowed down in matter. The energy loss is described by the stopping power, and the penetration depth in matter by the range.

2.1 Stopping Power

The stopping power of a target for a CP is the energy loss of the CP for an amount of target atoms. In CPAA it is most convenient to use mass stopping power, i.e. the energy loss per unit mass thickness, as given in Equation (1).

\[ S = \frac{-dE}{dx} \]  

where \( S \) is the mass stopping power, in MeV g\(^{-1}\) cm\(^2\); \( E \) is the energy, in MeV; and \( x = \rho l \), the mass thickness, in g cm\(^{-2}\) (\( \rho \) = mass density in g cm\(^{-3}\) and \( l \) = thickness in cm).

The stopping power is determined by the nature of the CP, energy of the CP, and nature of the target, as given in Equation (2).

\[ S_a = Z_a^2 S_p \left( \frac{E_a}{A_a} \right) \]  

where \( Z_a \) is the atomic number and \( A_a \) is the mass number. The subscripts “a” and “p” refer to a CP and proton, respectively. Figure 1(a) and Equation (2) show that the stopping power for 20-MeV deuterons is equal to the one for 10-MeV protons, and the stopping power for 30-MeV helium-3 particles and 40-MeV alpha particles is four times that of 10-MeV protons. The stopping power decreases with the CP energy (~1/E) (Figure 1b) and for increasing atomic number of the target (Figure 1c). This decrease is steep for low-Z targets.

Stopping power data for elemental matter can be calculated based on the Bethe formula. For mixtures, the additivity rule of Bragg and Kleeman (Equation 3) is applied.

\[ S = \sum_{i=1}^{n} w_i S_i \]  

where \( w_i \) is the mass fraction of the \( i \)th component, \( S_i \) is the mass stopping power of the \( i \)th component, and \( n \) is the number of components. For compounds, deviations from the Bragg rule may occur due to chemical binding effects. For the energy range of interest in CPAA (~1 MeV) these deviations can be neglected.

2.2 Range

As a consequence of the stopping power phenomenon, CPs lose their energy and are stopped at a depth called the “range”. From Equation (1) the mass range, \( R \), for a...
Figure 1(a) and Equation (5) show that the range of 20-MeV deuterons is twice that of 10-MeV protons, the range of 30-MeV helium-3 particles is 75% that of 10-MeV protons, and the range of 40-MeV $\alpha$-particles is equal to that of 10-MeV protons. The range increases with the CP energy ($\sim E^2$) (Figure 1b) and for increasing atomic number of the target (Figure 1c). The increase is steep for low-Z targets.

For CPAA the CP interaction with matter can be described simply: CPs traverse the target undeflected (i.e. nearly straight lines), the beam intensity (the number of CPs per unit time) is almost unchanged, and all CPs are stopped at the same depth in the target (at the range). Consequently, linear versus projected range, and range straggling, should not be considered for CPAA.

3 CHARGED PARTICLE INDUCED NUCLEAR REACTIONS

CPAA is based on a nuclear reaction $A + a \longrightarrow B + b + Q$, or $A(a,b)B$, where $A$ is the stable target nuclide (at rest), “a” is a CP (accelerated), B is a radionuclide, “b” is the particle(s) or photon emitted, and $Q$ is the $Q$-value. Two important characteristics are the minimum CP energy required to induce such a nuclear reaction, and the probability that this reaction will proceed. As CPs are slowed down when traversing matter, as described in section 2, the latter characteristic should be known as a function of the CP energy.

3.1 $Q$-value and Threshold Energy

The $Q$-value is the energy released by one single nuclear reaction. It is related to the difference between the resting masses of reactants and products, as given in Equation (6).

$$Q = (m_A + m_a - m_B - m_b)c^2$$

where $m$ is the nuclidic mass and $c$ is the velocity of light. Nuclidic masses can be replaced by atomic masses,
as electron masses are cancelled, at least if this also is done for “a” and “b” (e.g. for a (p,d) reaction the atomic masses of $^1$H and $^4$He, respectively, are used). A nuclear reaction can be endoergic ($Q < 0$) or exoergic ($Q > 0$).

To induce endoergic reactions the CPs should have a minimum energy, i.e. the threshold energy $E_t$, which is slightly higher than $-Q$. The compound nucleus, formed by collision of the CP “a” and the target nucleus A, retains a fraction of the kinetic energy of the CP, i.e. $m_a/(m_A + m_a)$. This fraction is “lost” to compensate for the shortfall of mass or energy for an endoergic reaction.

Approximating the nuclidic mass by the mass number $A$ for the recoil energy correction, the threshold energy is given by Equation (7).

$$E_t = \frac{A_A + A_a}{A} Q \quad \text{for } Q < 0$$
$$E_t = 0 \quad \text{for } Q \geq 0$$

where $E_t$ is the threshold energy. For exoergic nuclear reactions the threshold energy is zero by definition.

$Q$-values and threshold energies can be calculated from the Audi and Wapstra “adopted masses” 1993 or 1995 with the on-line program Q-calc, at the Lund Nuclear Data WWW Service (Lund University, Sweden), at the National Nuclear Data Center (NNDC, Brookhaven National Laboratory, USA), and at the International Atomic Energy Agency (IAEA, Austria), or as a Fortran-77 program for a VAX-VMS system.

### 3.2 Coulomb Barrier

The Coulomb barrier also determines the minimum CP energy needed to induce a nuclear reaction. The coulombic repulsive force between the target nucleus and the CP dominates at “large” distances, and increases when the CP approaches the target nucleus. At some particular distance (i.e. the sum of the radii of CP and target nucleus) the attractive nuclear force balances the Coulomb repulsive force. The decrease in the CP kinetic energy is given by the Coulomb barrier, as in Equation (8).

$$E_C \approx \frac{A_A + A_a}{A} \frac{Z_A Z_a}{\sqrt{A_A} + \sqrt{A_a}}$$

where $E_C$ is the Coulomb barrier, in MeV; and $\sqrt{A}$ is proportional to the nucleus radius. The Coulomb barrier for $^3$He and $^4$He particles is about twice as high as that for protons or deuterons, and it increases with the atomic number of the target nucleus, roughly $Z^2$, as shown in Figure 2.

The kinetic energy – the CP lost by the Coulomb barrier – is released again when a nuclear reaction occurs. Consequently, the Coulomb barrier influences the energetics of a nuclear reaction only in that a CP must have a kinetic energy higher than the Coulomb barrier before the reaction can occur. Quantum mechanical treatment of the problem explains that the reaction probability (see section 3.3) for CPs with a kinetic energy lower than the Coulomb barrier is not exactly zero, but very low, and rapidly drops as the CP energy decreases.

### 3.3 Nuclear Reaction Cross-section

The probability of a nuclear reaction is expressed as the (nuclear reaction) cross-section, which has the dimensions of area. This originates from the simple picture that the probability for a reaction between the target nucleus and the incident CP is proportional to the geometric cross-section that the target nucleus presents to a beam of CPs. The average cross-section is somewhere near $10^{-28} \text{ m}^2$. The barn (1 b = $10^{-28} \text{ m}^2$) is used as a unit for nuclear reaction cross-section.

The cross-section for a particular reaction (also called the partial reaction cross-section) depends on the energy of the CP. It is zero for CPs below the threshold energy of that reaction. If the Coulomb barrier is higher than the threshold energy (i.e. always the case for exoergic reaction, as $E_t = 0$ for $Q > 0$), then the cross-section is very low in the energy interval between the threshold energy and the Coulomb barrier. For CP energies exceeding the threshold energy and Coulomb barrier, the cross-section increases up to a maximum (typically 1 b), and decreases as more complex reactions become competitive. Two annotated examples are given in Figure 3(a) and (b).

### 3.4 Cross-section Data: Excitation Function and Activation Curve

As CPs are slowed down in matter, knowledge of the cross-section as a function of the energy is required.
for CPAA. However, absolute data are not required (sections 5.2 and 5.3). Therefore the excitation function (or curve) indicates the absolute cross-section as a function of the energy, while the activation curve indicates a relative data set.

Experimental excitation functions can be obtained from the EXFOR (or CSISRS) database at NNDC mirrored at IAEA and the Nuclear Energy Agency (NEA), France.\(^7\) For the data sets in Figure 3(a), obtained from this database, the agreement is fairly good, but this is not representative for the vast majority of CP induced reactions. Actually the \(^{14}\text{N}(d,n)^{15}\text{O}\) reaction has been studied in great detail, because it is extremely important for positron emission tomography (PET), an imaging technique for quantifying the oxygen metabolism, blood flow and blood volume in nuclear medicine.

If no experimental data are available, excitation functions can be estimated using the very simple equations and data from Keller et al.\(^8\)

The experimental procedure needed to obtain an activation curve is quite simple if the target element (A) is available as “thin” foil. “Thin” means much smaller than the range. A stack of “thin” foils (total thickness \(\geq\) range) is irradiated, and the foils are measured individually. After decay correction the count rate measured is proportional to the cross-section, as will be shown in Equation (17). Excitation function data require absolute activity measurements, absolute beam intensity monitoring, and absolute energy measurement of the incident CP beam. However, an activation curve (relative cross-section data) is sufficient for CPAA.

In contrast to neutron induced reactions, no experimental data are available for most of the CP induced reactions. Additionally, if different data sets are available, their agreement is often unsatisfactory. Therefore approximate methods for standardization have been developed in CPAA.

### 3.5 Radionuclides Formed by Charged Particle Induced Reactions

Which radionuclides are formed by irradiation of a particular matrix by a CP with a particular energy, and what is their approximate activity level?

The first question can be answered by observing a chart of nuclides. This represents all nuclides with relevant data for CPAA as chemical symbol, mass number, isotopic abundance (stable nuclides), half-life, decay mode, and decay energies (radioisotopes). For proton irradiation, for example, the reaction types given in Figure 4 should be applied to all stable isotopes of all elemental components of the matrix. In the inventory of possible nuclear reactions two categories can be rejected: those leading to stable nuclides, and those with a threshold energy higher than the CP energy. Reactions for which the Coulomb barrier is higher than the CP energy induce only low activity levels, but cannot be excluded. An annotated example is given in Figure 4 for a 10-MeV proton irradiation of nitrogen.

The induced activity is proportional to the number of CPs per time unit, irradiation time (not linearly), number of target nuclides, and reaction cross-section. The number of target nuclides is inversely proportional to the relative atomic mass of the element, and proportional to the mass fraction of the element in the target, the isotopic abundance of the target nuclide, and the activated depth, i.e. the range of the target at the incident energy minus

---

**Figure 3** Excitation functions. (a) The \(^{14}\text{N}(d,n)^{15}\text{O}\) reaction is exoergic \((Q > 0)\), consequently its threshold energy is zero. Below the Coulomb barrier (2.2 MeV) the cross-section is low, but not zero. It increases steeply around the Coulomb barrier energy. (b) The \(^{56}\text{Fe}(p,n)^{56}\text{Co}\) reaction is endoergic \((Q < 0)\), consequently its threshold energy is zero. Below the Coulomb barrier (2.2 MeV) the cross-section is low, but not zero. It increases steeply around the Coulomb barrier energy.
NUCLEAR METHODS

**Figure 4** (a) Reaction scheme for proton irradiation to be applied to a chart of nuclides. In general, for a proton energy below 10 MeV only the \((p,n)\) and \((p,\alpha)\) reactions have to be considered; for a proton energy up to 20 MeV the \((p,2n), (p,d), (p,t), (p,^3He), \) and \((p,\alpha n)\) reactions also have to be taken into account. (b) Part of a chart of nuclides: irradiation of nitrogen by 10-MeV protons mainly induces \(^{14}\text{O}\) and \(^{11}\text{C}\) by a \((p,n)\) and \((p,\alpha)\) reaction, respectively, from \(^{14}\text{N}\), i.e. the most abundant stable isotope of nitrogen, and to a negligible extent \(^{15}\text{O}\) by a \((p,n)\) reaction from \(^{15}\text{N}\). The \((p,\alpha)\) reaction has not been considered for CPAA as it produces \(^{12}\text{C}\), a stable nuclide.

the range at the threshold energy or the Coulomb barrier, whichever is higher. This will be treated in more detail in section 5.1. A rough estimate of the induced activity, i.e. the thick target yield (TTY), can be calculated from Equation (9).

\[
A \approx 380 \frac{1}{Z_a} I \frac{1}{A_t} w \theta (1 - e^{-\lambda t_i}) \frac{R_{E_i}}{R_{E_i/C}} e^{-\lambda t_w} \tag{9}
\]

where

- \(A\) = activity, in kBq,
- \(Z_a\) = atomic number of the CP (1 for p and d; 2 for \(^3\text{He}\) and \(^4\text{He}\) \((\alpha\)-particles)),
- \(I\) = beam intensity, in \(\mu\)A,
- \(A_t\) = relative atomic mass of the target element,
- \(w\) = mass fraction of the target element in the matrix, in \%,
- \(\theta\) = isotopic abundance, in atom \%,
- \(\lambda\) = \(\ln(2)/t_{1/2}\), decay constant of the radionuclide (where \(t_{1/2}\) is the half-life),
- \(t_i\) = irradiation time,
- \(t_w\) = waiting time,
- \(\bar{\sigma}\) = average reaction cross-section, in mb (generally, \(100 < \bar{\sigma} < 1000\)),
- \(R\) = mass range, in g cm\(^{-2}\) (section 2.2 and Figure 1),
- \(E_i\) = incident energy,
- \(E_{i/C} = \max(E_i, E_C)\) (sections 3.1 and 3.2).

An example of the TTY as a function of the incident energy is given in Figure 3(b) for the \((p,n)\) reaction.

A chart of nuclides is available as:

- a wall chart or booklet,
  - Kernforshungszentrum Karlsruhe (Germany), (see reference 9)
  - General Electric & KAPL, Knoll Atomic Power Lab. (USA),\(^{10}\)
- a PC program,
  - NuChart from IAEA (1994), no further updates,\(^{11}\)
  - Nucleus from AMDC, Atomic Mass Data Center (France),\(^{12}\)
  - MacNuclide from Center for Nuclear Information Technology (for Mac),\(^{13}\)
- a PC program in combination with a database on the internet, Isotope Explorer (formerly VuENSDF) from LBNL, Lawrence Berkeley National Laboratory (USA) and Lund University (Sweden),\(^{14}\)
- on-line databases on the internet,
  - Lund Nuclear Data WWW Service from Lund University (Sweden),\(^{15}\)
  - jvNuBase from AMDC, Atomic Mass Data Center (France),\(^{16}\)
  - KAERI Table of the Nuclides from KAERI, Korea Atomic Energy Research Institute (also mirrored).\(^{17}\)

### 4 INTERFERENCES

The determination of an analyte element is based on the reaction \(A(a,b)B\), where \(A\) is a stable nuclide of that analyte element and \(B\) is a radionuclide (section 3). Three different types of interference can be distinguished: nuclear, spectral, and matrix.

#### 4.1 Nuclear Interference

A radionuclide \(B\) is also formed from an element other than the analyte element by a nuclear reaction \(C(c,d)B\). \(C\) is a stable nuclide of the interfering element.
The CP “c” is mostly identical to “a”, but nuclear interferences induced by secondary particles, e.g. fast or thermalized neutrons produced by (a,n) reactions, have to be considered also. Nuclear reactions can only be avoided by a proper choice of the CP energy if the threshold energy $E_t$ of the interfering reaction $C(c,d)B$ exceeds both the threshold energy and the Coulomb barrier of the analyte reaction $A(a,b)B$. To obtain high sensitivity, the CP energy is chosen at or just below the threshold energy of the interfering reaction.

Interference by the $^{14}\text{N}(d,t)^{13}\text{N}$ reaction (Figure 4b) could affect the determination of carbon by the $^{12}\text{C}(d,n)^{13}\text{N}$ reaction. As the threshold energy of the interfering reaction (4.9 MeV) exceeds that of the analyte reaction (0.3 MeV), as well as the Coulomb barrier (2.0 MeV), carbon can be determined sensitively and interference free by irradiation with 4.9-MeV deuterons. It is obvious that the difference in Coulomb barrier is largely insufficient to avoid nuclear interferences, and that the reaction $^{13}\text{C}(d,2n)^{11}\text{N}$ does not interfere with the determination of carbon.

### 4.2 Spectral Interference

A radionuclide D is formed by the nuclear reaction $C(c,d)D$ and the measurement does not resolve the activity of B and D. Spectral interferences can be avoided by:

1. The proper choice of the incident CP energy with respect to the threshold energy and the Coulomb barrier (analogous to nuclear interference).
2. Selective measurement of the radionuclide D with respect to radionuclide B by spectrometry or decay curve analysis (sections 7 and 9.2). The former is possible if the $\gamma$-lines differ by more than the energy resolution of the spectrometer used. The latter is possible if the half-lives of the radionuclides C and D are sufficiently different (about a factor of 2 for comparable activities). If D is short-lived, i.e. its half-life is $>10$ times lower as compared to B, then selective measurement (interference < 0.4%) is possible for an irradiation and waiting time equal to one half-life of B (for comparable relative atomic mass, mass fraction, isotopic abundance, cross-section, and range, Equation 9).
3. Radiochemical separation of B from D, if both are not radioisotopes, i.e. radionuclides of the same element (section 8.4).

Nitrogen can be determined by the $^{14}\text{N}(p,n)^{12}\text{O}$ as well as by the $^{14}\text{N}(p,n)^{13}\text{N}$ reaction (Figure 4b). The former reaction leads to $^{14}\text{O}$, a $\beta^+$- $\gamma$-emitter. Measuring the 2313-keV $\gamma$-ray with a Hewlett-Packard Ge spectrometer, the former reaction only undergoes interference by other $\gamma$-emitters within the energy resolution ($\approx 2$ keV) of that spectrometer. There could be interference with the latter reaction by, for example, the $^{13}\text{C}(p,n)^{12}\text{N}$, $^{14}\text{N}(p,n)^{14}\text{O}$, $^{15}\text{N}(p,n)^{15}\text{O}$, and $^{16}\text{O}(p,\alpha)^{13}\text{N}$ reactions, all leading to $\beta^+$ (positron) emitters. Measurement of their annihilation radiation (section 7.1) is aspecific and thus could cause spectral interference. As the threshold energies (3–6 MeV) and the Coulomb barriers are not sufficiently different, the interference cannot be avoided by a proper choice of the proton energy. Measurement of the activity as a function of time followed by decay curve analysis (section 9.2) leads to the initial activity of each component if the activity levels are comparable within 1 to 3 orders of magnitude. It is obvious that the other reactions [(p,n), (p,\alpha)] on the analyte element (N) also cause spectral interference (in contrast to nuclear interference). Alternatively, $^{13}\text{C}$ can be radiochemically separated by combustion in oxygen and trapping of the carbon dioxide formed, as the other radionuclides are not radioisotopes of carbon. The latter is called radiochemical analysis (section 8.4) or determination, in contrast to instrumental analysis.

### 4.3 Matrix Interference

Matrix interference is a special case of spectral interference. As CPAA is primarily a method for trace element determinations or thin-layer characterization, the activity level of the main matrix components could be several orders of magnitude higher than the activity of the analyte element, e.g. $10^6$ for a trace element determination at the $\mu$g g$^{-1}$ or ppm level. Then instrumental analysis is almost impossible, even for quite different $\gamma$-energies and/or half-lives. Instrumental analysis is only possible for a proper choice of the CP energy, as an alternative for a highly specific radiochemical separation. It is obvious that the determination of light elements (boron, carbon, nitrogen, oxygen) in a high-Z sample is favored by the Coulomb barrier (section 3.2).

### 5 STANDARDIZATION

Standardization or calibration in CPAA is performed in a relative way, i.e. a sample and a standard are both irradiated and measured. To preserve the advantage of CPAA as an “absolute” or “independent” method, there is no need for a standard similar to the sample and certified for the analyte concentration or mass thickness. The standard is pure elemental matter or a pure compound with exactly known stoichiometry (section 8.1). In a relative method there is no need for absolute data, and errors are cancelled.
For trace element determination in the bulk of a sample, the experimental data (activity) are related to the mass fraction (or concentration) expressed in, for example, mg kg\(^{-1}\) (SI), \(\mu g\) g\(^{-1}\), ppm (parts per million) or \(\mu g\) kg\(^{-1}\), ng g\(^{-1}\), ppb (parts per billion).

Surface characterization of thin layers stands for the determination of the partial mass thickness. For an Al\(_2\)O\(_3\) layer the partial/total mass thickness is the amount of Al/Al\(_2\)O\(_3\) per surface unit, expressed in \(\mu g\) cm\(^{-2}\). From the partial mass thickness the total mass thickness, or thickness or composition (mass fraction or stoichiometry), can be calculated (section 10).

As standardization for trace element determinations in the bulk of a sample and surface characterization have a common and a specific part, the following is divided into three sections. The word “target” will be replaced by “sample” or “standard” in sections 5.2 and 5.3.

### 5.1 General

The number of radionuclides produced per unit time by irradiation of an infinitesimally thin target is determined by the balance of the increase due to nuclear reactions (proportional to the number of CPs per unit time (i.e. beam intensity, the cross-section and the number of target nuclides per surface unit)) and the decrease due to radioactive decay (\(-\lambda N\)) (Equation 10).

\[
\frac{dN}{dt} = Ion \, dl - \lambda N \tag{10}
\]

where

- \(N\) = number of radionuclides,
- \(t\) = time,
- \(I\) = number of CPs per unit time or beam intensity,
- \(\sigma\) = partial nuclear reaction cross-section,
- \(n\) = number of target nuclides per unit volume,
- \(l\) = thickness of the target,
- \(\lambda = \ln(2)/t_{1/2}\), decay constant of the radionuclide formed (where \(t_{1/2}\) = half-life).

From Equation (10), the number of radionuclides formed and the induced activity after an irradiation time \(t\) can be calculated. On condition that the beam intensity is constant, this yields Equation (11).

\[
A = \lambda N = Iw \frac{1}{M} \, N_A \theta \left(1 - e^{-\lambda t}\right) \sigma \, dx \tag{11}
\]

where

- \(A\) = activity in Bq,
- \(w\) = mass fraction of the activated element in the target,
- \(M\) = molar mass of the activated element,
- \(N_A\) = Avogadro’s constant,
- \(\theta\) = isotopic abundance of the target nuclide,
- \(t_i\) = irradiation time.

A CP beam is stopped completely in a “thick” target, in which the mass thickness \(D\) is at least equal to the range \(R\). To calculate the activity for such a “thick” target one has to integrate \(\sigma \, dx\) in Equation (11), using the stopping power (Equation 1), as the cross-section has to be expressed as a function of the energy. The calculation is given by Equation (12).

\[
R \int_0^l \sigma \, dx = \int_0^l \frac{\sigma \, dE}{E_i} \, dx = \frac{\sigma}{E_i} \frac{dE}{ds} \tag{12}
\]

where \(R\) is the mass range of the CP in the target, in g cm\(^{-2}\); \(E_i\) is the incident CP energy, in MeV; \(E_s\) is the threshold energy, in MeV; and \(S\) is the mass stopping power, in MeV g\(^{-1}\) cm\(^2\). The integration limit \(E = 0\) (corresponding to \(x = R\)) may be replaced by the threshold energy \(E_i\), as the cross-section is zero for \(E < E_i\).

If the excitation function is not known, an energy \(E_{i/C}\) can be defined as the maximum of threshold energy and Coulomb barrier. The cross-section can be supposed to be zero below \(E_{i/C}\), while above \(E_{i/C}\) it is constant. Then the following approximation (Equation 13) is obtained from Equations (2) (range definition) and (12).

\[
R \int_0^l \sigma \, dx = \frac{E_i}{E_i} \frac{\sigma}{E_i} \frac{dE}{ds} \approx \overline{\sigma} (R_{E_i} - R_{E_{i/C}}) \tag{13}
\]

if \(\sigma(E) = 0\) for \(0 < E < E_{i/C}\); and \(\sigma(E) = \overline{\sigma}\) for \(E_{i/C} < E < E_i\); where \(\overline{\sigma}\) = average cross-section, and \(E_{i/C} = \max(E_i, E_C)\).

From Equations (11), (12), and (13) the activity induced in a thick target (i.e. TTY) is given by Equation (14), which approximates to Equation (15).

\[
A = Iw \frac{1}{M} \, N_A \theta \left(1 - e^{-\lambda t_i}\right) \sigma (R_{E_i} - R_{E_{i/C}}) \tag{14}
\]

\[
A \approx Iw \frac{1}{M} \, N_A \theta \left(1 - e^{-\lambda t_i}\right) \overline{\sigma} (R_{E_i} - R_{E_{i/C}}) \tag{15}
\]

The target is assumed to be homogeneous, and the decrease in beam intensity (due to nuclear reactions) is negligible. Consequently, neither \(w\) nor \(I\) is a function of \(x\) or \(E\).

For a “thin” target, i.e. a target that nearly reduces the CP energy, where the mass thickness \(D\) is much lower than the mass range \(R\), the induced activity is given by Equation (16), which approximates to Equation (17).

\[
A = Iw \frac{1}{M} \, N_A \theta \left(1 - e^{-\lambda t_i}\right) \frac{E_i}{E_s} \frac{\sigma}{E_s} \tag{16}
\]

\[
A \approx Iw \frac{1}{M} \, N_A \theta \left(1 - e^{-\lambda t_i}\right) \sigma \theta D \tag{17}
\]
where $E_o \approx E_i$, the outgoing energy, in MeV; $\sigma_0$ is the cross-section for $E_o < E < E_i$; and $D \ll R$, the mass thickness of the “thin” target, in g cm$^{-2}$.

### 5.2 Trace Element Determination in the Bulk of a Sample

A relative method is applied, whereby a “thick” sample and a “thick” standard are irradiated and measured separately. As the nature of sample and standard is different, a correction, $F$, has to be made owing to the different stopping power (or range) of sample versus standard. Applying Equations (14) and (15) for, respectively, a sample “x” and a standard “s”, and assuming the sample and standard to have equal natural abundance, the mass fraction of the analyte in the sample yields Equation (18), in which $F$ is given by Equation (19), which approximates to Equation (20). (To comply with SI the “mass fraction” $w$ is used, while in the CPAA literature often “concentration” $c$ is used.)

\[
w_x = w_s \frac{A_x I_x (1 - e^{-\lambda_{x} t})}{A_s I_s (1 - e^{-\lambda_{s} t})} F\]  

(18)

where the subscripts x and s refer to a “thick” sample, and a “thick” standard, respectively.

\[
F = \frac{E_x \sigma dE}{E_s \sigma dE} \frac{S_x}{S_s} \]  

(19)

\[
F \approx \frac{(R_{E_i} - R_{E_{i,c}})_x}{(R_{E_i} - R_{E_{i,c}})_s} \]  

(20)

The mass fraction (concentration) of the analyte in the sample $w_x$ can be calculated from:

- the mass fraction of the analyte element in the standard $w_s$,
- the ratio of the activity in sample and standard at the end of irradiation $A_x/A_s$,
- the ratio of the beam intensity for standard and sample $I_s/I_x$,
- the decay constant of the radionuclide formed $\lambda$,
- the F-factor, i.e. a correction for different stopping power of sample versus standard.

The F-factor can be calculated exactly by Equation (19), requiring:

- relative cross-section data $\sigma$ from the threshold energy $E_i$ up to the incident energy $E_i$,
- relative stopping power data for standard and sample $S_s, S_x$ in the same energy interval.

If no cross-section data are available, the F-factor can be approximated by Equation (20). This approximation yields quite good results if one or more of the following conditions (in decreasing order of importance) are fulfilled:

- the atomic number of sample and standard are similar,
- the threshold energy or the Coulomb barrier for the nuclear reaction is high,
- the incident energy is high.

The “atomic number” of a compound is, in principle, that of the element with the same stopping power. Practically, the atomic numbers of the elemental components can be averaged: mass fraction weighed. For simplicity Equation (13) was derived supposing a “step-wise” excitation function, which does not agree with reality. A detailed study\(^{18}\) showed that this approximation can also be obtained by assuming that $S_s/S_x$ is a constant as a function of the energy. If the above mentioned conditions are fulfilled, the latter assumption holds better, as can be observed from the parallel lines in Figure 1(b).

Several approximate methods, not requiring cross-section data, have been proposed and evaluated.\(^{18}\) Equation (19) is known as the first method of Ricci and Hahn.\(^{19}\) The second method of Ricci and Hahn\(^{20}\) is fundamentally false. The method of Chaudri et al.\(^{21}\) yields nearly the same approximation as the first method of Ricci and Hahn. Chaudri’s method makes use of stopping power data instead of range data, as shown in Equation (21).

\[
F \approx \frac{(S_{Em})_x}{(S_{Em})_s} \]  

(21)

where $E_M = (E_i + E_{(C)}/2$. The “average stopping power method” is an outstanding approximate method with a negligible error that can be calculated.\(^{22,23}\) However it needs cross-section data, and therefore there is no reason to prefer it to Equation (19). The method has more intellectual than practical merits.

The internal standardization method, not requiring stopping power data for the sample, has more practical applications.\(^{24}\) The major composition of a sample is often not known, or the composition changes during irradiation. Samples can lose their organic fraction due to heating, and consequently positive errors are made because the stopping power of hydrogen is 3–5 times higher than for the other elements (Figure 1c). Also, approximate methods not requiring cross-section data have been proposed.

The “two reactions method” does not require stopping power data.\(^{25}\) Its main advantage is that accuracy of the
method is not influenced by the accuracy of the stopping power data. Experimentally, the method is quite complex.

Also, the standard addition method does not require stopping power data.\textsuperscript{126,27} As CPAA is mainly intended for solid samples, the applicability of this method is limited to powdered samples.

A critical review is given by Strijckmans.\textsuperscript{28}

5.3 Surface Characterization of Thin Layers

As for trace element determinations, a relative method is also applied. A “thin” surface layer is irradiated and measured together with a “thin” or “thick” standard. From Equations (16) and (17) the partial mass thickness, using a “thin” surface layer and a “thin” standard, respectively. Equation (24) can be obtained from Equations (14), (15), and (17) for a “very thin” standard used.

\[ w_D D_x = w_x A_x I_x (1 - e^{-\lambda h_x}) A_x I_x (1 - e^{-\lambda h_x}) \]  \hspace{1cm} (22)

\[ w_D D_x \approx w_x A_x I_x (1 - e^{-\lambda h_x}) A_x I_x (1 - e^{-\lambda h_x}) \]  \hspace{1cm} (23)

where \( wD \) is the partial mass thickness; \( D \ll R \), the total mass thickness; and the subscripts \( x \) and \( s \) refer to a “thin” surface layer and a “thin” standard, respectively.

For a “thin” surface layer (order of magnitude \( \mu \) to nm) the approximation made in Equation (17) holds. For the “thin” standard (order of magnitude 10 to 100\( \mu \)) one has to check if the cross-section is still constant in the energy interval \( E_0 - E_i \). Although Equation (23) does not contain cross-section data, a knowledge of such data, at least relatively in the above mentioned interval, is required in order to evaluate the equation’s applicability.

If thin standards are not available, analogous formulae can be obtained from Equations (14), (15), and (17) for a “thick” standard. The partial mass thickness using a “thick” standard yields Equation (24), which approximates to Equation (23).

\[ w_D D_x = w_x A_x I_x (1 - e^{-\lambda h_x}) A_x I_x (1 - e^{-\lambda h_x}) \]  \hspace{1.2cm} (24)

\[ w_D D_x \approx w_x A_x I_x (1 - e^{-\lambda h_x}) A_x I_x (1 - e^{-\lambda h_x}) \]  \hspace{1.2cm} (25)

where the subscripts \( x \) and \( s \) refer to a “thin” surface layer and a “thick” standard, respectively. Equation (24) requires at least relative cross-section data. From Equation (25) no approximation can be written that does not require cross-section data. The average cross-section in the energy interval \( E_{i/c} \) to \( E_i \) is never comparable to the cross-section at the incident energy (actually in the very narrow interval \( E_0 \) to \( E_i \)). For trace element analysis in the bulk of a sample such an approximation was possible (section 5.2, and Equations 18 and 20), and it results in accurate analyses observing the conditions mentioned in section 5.2.

5.4 Conclusions

The standardization formulae to be used are summarized in Table 1. For trace element determinations in the bulk of a sample (mass fraction), accurate results can be obtained without a knowledge of cross-section data if one or more of the conditions are fulfilled. For surface characterization (mass thickness determination) accurate results can also be obtained without a knowledge of cross-section data if a “very thin” standard is used.

6 CHARGED PARTICLE IRRADIATION

6.1 Accelerator

CPs have to be accelerated to an energy higher than the Coulomb barrier and lower than the threshold energy of reactions that are more complex than (\( a,n \)) and (\( a,\alpha \)). The lower limit is to obtain high reaction cross-sections, and consequently high sensitivity; the upper limit is to avoid nuclear interferences by these complex reactions. For protons and deuterons the ideal energy range should be 5–25 MeV, while for helium-3 and \( \alpha \)-particles it should be twice as high. A cyclotron is an ideal accelerator for this energy range, although a tandem Van de Graaff also covers the lower energy range.\textsuperscript{29}

A tandem Van de Graaff is a DC linear accelerator, the DC source being an electrostatic Van de Graaff generator. The tandem principle is related to the use of the same voltage to accelerate the particles (e.g. protons) twice. First, negative hydrogen ions (\( H^- \)) are accelerated to
5 MeV by applying 5 MV from the electrostatic generator; then the ion is stripped from its electrons, and the same reversed voltage is applied again to accelerate to 10 MeV.

The tandem principle is applied a thousand-fold in AC accelerators. A cyclotron is an AC circular accelerator. A high-frequency electric field accelerates the CPs, following a spiral path, due to the magnetic field applied. Ideally, an isochronous cyclotron should be a multiparticle and variable energy accelerator. This implies that the magnetic field and the high-frequency electric field can be tuned, and that the magnetic field as a function of the radius can be adjusted (to compensate for relativistic mass increase during acceleration). Typically, an isochronous cyclotron has radial or spiral sectors in the magnet poles, a prerequisite for beam focusing. Cyclotrons that accelerate helium-3 particles should be equipped with a recuperation system. Typically, the energy can be tuned by a factor of 5–10.

However, the vast majority of cyclotrons in the world is the two-particle and fixed energy type, the so-called “baby cyclotron”. Their high-frequency electric and magnetic fields are fixed, and the magnetic field increases with the radius by the shape of the magnet poles. Protons or deuterons can be accelerated, the deuteron energy being half the proton energy. Such cyclotrons are negative-ion machines (H⁻ ions are accelerated, stripped, and the protons formed leave the magnetic field). Extraction of negative ions with a stripping foil is technically very simple compared to extraction of positive ions. These are extracted with a deflector: a strong DC electric field “extracts” the accelerated beam out of the magnetic field. The stripping foil (in contrast to a deflector) can be moved into the cyclotron, extracting a lower energy beam. Energy tuning of up to a factor of 2 is possible. Baby cyclotrons are widely used in nuclear medicine departments for PET, i.e. a functional imaging technique using biologically active molecules labeled with cyclotron-produced, short-lived positron emitters.

The beam requirements are not very severe. The energy should be well-defined (within 0.1 MeV is largely sufficient) to control interferences by their threshold energy and/or Coulomb barrier. The beam energy should be reproducible within several days, because this influences slightly the sensitivity. The beam intensity should be tunable from 0.01 to 5 μA, which is largely under the upper limit of these accelerators, and kept constant during irradiation (Equation 11 was calculated assuming that the beam intensity is constant). The unfavorable beam characteristics of a cyclotron versus a Van de Graaff accelerator, such as pulsed beam and energy resolution, are of no importance in CPAA.

6.2 Heat Release in a Target
CP irradiation can cause substantial heating to the sample. Indeed, standards can be irradiated for shorter times and/or at lower beam intensity. The heat release (power) in a “thick” target is given by the energy of one single CP multiplied by the number of CPs per unit time (Equation 26).

\[ Q = \frac{EI}{Z_a} \]  

where

- \( Q \) = heat release (power), in W;
- \( E \) = CP energy, in J;
- \( I \) = beam intensity, in A;
- \( Z_a \) = atomic number of the CP;
- \( e \approx 1.6 \times 10^{-19} \) C (the elementary charge);

or more practically, according to Equation (27),

\[ Q = \frac{EI}{Z_a^2} \]  

where

- \( Q \) = heat release (power), in W;
- \( E \) is the CP energy, in MeV; and \( I \) is the beam intensity, in μA. For a “thin” target \( E \) should be replaced by the energy decrease for the CP traversing the sample, which can be written as the mass thickness of the target and its stopping power (Equation 28).

\[ Q = \frac{(E_i - E_o) I}{Z_a} = \frac{SD}{Z_a} \]  

where

- \( E_i \) is the incident energy, in MeV; \( E_o \) is the outgoing energy, in MeV; \( S \) is the mass stopping power, in MeV g⁻¹ cm²; \( D \) is the mass thickness of the “thin” target, in g cm⁻².

Heat is not released uniformly in the sample. It is obvious that the volume is determined by the irradiation surface and the CP range in the target. The depth distribution is given by the stopping power, as shown in Figure 5 for 10-MeV protons in a “thick” aluminum target. One can observe the Bragg peak at the very low energy side, i.e. for a depth approaching the range. Two conclusions can be drawn. For “thick” targets, heating is more pronounced at the lower energy side, i.e. below the Coulomb barrier, and consequently not in the activated (and thus analyzed) part of the sample. The most efficient back-side cooling is for a sample thickness not exceeding the range. Remember that for trace element determinations in the bulk of a sample one has to always irradiate “thick” samples and standards. For surface characterization of thin layers (nm to μm) the heat release is several orders of magnitude lower. It is obvious that also the heat release in the substrate should be considered.

6.3 Target Holder

CPAA has been applied for solid samples (massive or powdered), such as semi-conductors, metals and alloys, ceramics, geological materials, and solid environmental samples (aerosols, soils). It has not been applied for aqueous solutions because optical (atomic) and mass spectrometric methods of analysis are much more suited.

A simple target holder design is a water cooled copper or aluminum base plate, on which a “thick target” is mounted, that can be irradiated in the vacuum system of the cyclotron. For surface characterization, the target should be backed (e.g. by aluminum for proton activation) to obtain “thick” target conditions, and so avoid activation of the target holder. For powdered samples with poor thermal conductivity, irradiation in a helium atmosphere is recommended. An annotated example is shown in Figure 6.

6.4 Direct Beam Intensity Monitoring

Although the beam intensity I is quantified a posteriori by I-monitors (see below), direct I-monitoring is necessary to keep it constant during irradiation, a prerequisite for obtaining Equation (11). Therefore the target holder should be electrically insulated (>1010 Ω) from the beam transport system. Moreover, the cooling water should be deionized, as this is the case for the cooling system of the cyclotron. The target holder (i.e. A + B or A + C in Figure 6) is connected to the ground by an ammeter that will measure in the µA range, as shown in Figure 7(a). During irradiation the target tends to charge positively.

Figure 5

Figure 6 Target system for irradiation in a helium atmosphere. A titanium foil separates the vacuum of the cyclotron from the helium atmosphere. A powdered target is loaded in a dedicated target holder (B), together with a beam intensity monitor foil and an aluminum foil. A disk target is loaded in a dedicated target holder (C), together with a beam intensity foil and an aluminum foil. Powders are loaded from the back-side (B) and, after irradiation, quantitatively unloaded from the front side. Disk targets with good thermal conductivity are also water cooled from the back-side. The target holder (B or C) is brought in a water cooled set-up (A), which is evacuated and filled with helium. (Reproduced by permission of Elsevier Science, from N. De Brucker et al., Anal. Chim. Acta, 220, 93–102 (1989).)
which is balanced by the “electron” current measured. By impact of the CPs on the target, secondary electrons are emitted towards grounded parts (e.g. diaphragm) of the beam transport system, which causes positive systematic errors in the \( I \)-measurement. To avoid emission of secondary electrons (and their positive systematic errors for \( I \)-measurement) two experimental set-ups are used. A ring-shape electrode at negative potential (\(-100 \text{ V}\), as the electron energy does not exceed 100 eV) is inserted between the diaphragm and the target, as shown in Figure 7(b). Alternatively, the target holder is electrically connected to a tube, preventing the escape of secondary electrons over a wide spatial angle, as shown in Figure 7(c). A suitable diaphragm prevents the beam from hitting both devices as well as the target holder itself.

6.5 Quantitative Beam Intensity Monitoring

Knowledge of the ratio of the beam intensity for standard and sample (Equations 18, 22–24) is necessary for quantitative analysis in CPAA. There are three reasons for not using direct beam intensity measurement: (1) no absolute beam intensity data are required, (2) to obtain accurate data (no systematic errors due to secondary electrons and/or due to the beam hitting the target holder), and (3) to obtain precise data at low beam intensities (which is mostly the case for standards) compared to the blank. Sample and standard are covered prior to irradiation with a “thin” foil (i.e. \( I \)-monitor) of exactly the same thickness. After irradiation both \( I \)-monitor foils are measured. From Equation (17) the ratio of beam intensities, \( I_s/I_x \), is given.

Figure 7 Direct beam intensity monitoring:\(^{28}\) emission of secondary electrons causes systematic positive errors (a) that can be avoided by a ring shape electrode at negative potential (b) or a tube preventing escape of secondary electrons over a wide spatial angle (c). 7 ACTIVITY MEASUREMENT

Section 7.1 explains which radionuclides are formed by CP induced reactions, and gives arguments for measuring \( \gamma \)-spectra, where possible. If this is not possible, measuring the decay curve of annihilation radiation is described. Sections 7.2 and 7.3 give more details about instrumentation.

7.1 Radionuclides Formed and Decay Radiation

Measured in Charged Particle Activation Analysis

CP induced reactions produce radionuclides that decay by positron emission and/or electron capture (EC) because they contain one proton in excess compared to stable nuclides. Figure 4(b) shows stable nuclides \( ^{12}\text{C} \), \( ^{14}\text{N} \), \( ^{16}\text{O} \), for which the number of protons (\( Z \)) equals the number of neutrons (\( A - Z \)). In contrast, \( ^{14}\text{O} \) formed by the \( ^{14}\text{N}(p,n)^{14}\text{O} \) reaction is unstable, because of an unbalanced proton/neutron number (8/6). \( ^{14}\text{O} \) decays by positron emission, i.e. transmutation of a proton into a neutron (that stays in the nucleus), a positron, and a neutrino, both of which are emitted. In this way a stable nuclide \( ^{14}\text{N} \) is formed again. A positron (\( \beta^+ \)) is a positive electron, the anti-matter of an electron. A neutrino has no charge and a negligible mass, and consequently is nearly impossible to detect. The difference in energy level between the unstable radionuclide \( ^{14}\text{O} \) and the excited state of the nuclide \( ^{14}\text{N} \) \( (1/\Delta E_{\text{ann}}) \) is randomly distributed between the positron and the neutrino. The excited state of \( ^{14}\text{N} \) further decays to the ground state by photon emission, i.e. \( \gamma \)-rays. Consequently, the energy spectrum of a positron is continuous, from zero to a specific maximum energy \( (E_{\text{ann}}) \), while \( \gamma \)-rays are mono-energetic. To identify radionuclides (i.e. qualitative analysis) specifically (i.e. without interferences), \( \gamma \)-spectrometry is preferred.

An alternative to positron emission is EC (or \( e \)). As the decay radiation produced is Auger electrons and/or X-rays, which can easily be absorbed by the sample itself, (in contrast to the \( \gamma \)-rays) they are not used in CPAA.

A limited number of positron emitters decay directly to the ground state without \( \gamma \)-emission. This is the case for the determination of light elements (boron, carbon, nitrogen, oxygen), which is actually the most important application of CPAA. As can be seen from Figure 4(b), the above mentioned reaction is an exception: \( ^{15}\text{O} \) \( (\gamma) \) (determination of N), \( ^{15}\text{N} \) \( (\gamma) \) (determination of C and N), and \( ^{11}\text{C} \) \( (\gamma) \) (determination of B and N) are all pure positron emitters. This is also the case for \( ^{18}\text{F} \) \( (\gamma) \) (determination of O).

Selective and sensitive measurement of positron emitters is possible by measuring their annihilation radiation. In positron annihilation a positron loses its kinetic energy, annihilates with an electron, and two annihilation photons (\( \gamma \)-rays) are emitted in opposite direction. According to the mass-energy equivalence law, their energy is 511 keV, corresponding to the mass of an electron at rest. It is obvious that the information about the characteristic maximum energy (and thus the identity of the radionuclide) is lost during the annihilation process. The positron emitter must now be identified by its characteristic half-life. Therefore the activity of a mixture of positron emitter(s) is measured as a function of time, i.e. the decay curve. Decay curve analysis is detailed in section 9.2.

7.2 \( \gamma \)-Spectrometry

\( \gamma \)-Spectrometry can be performed by an NaI scintillation detector and a Ge semiconductor detector. To reduce spectral interferences as much as possible, only a Ge detector is used because of its superior energy resolution characteristics compared to the NaI detector. The Ge detector is a diode, reverse biased. One \( \gamma \)-ray interacts with the detector by Compton scattering or the photoelectric effect. The photo- or Compton electron formed causes ionization in the detector and many electron–positive-hole pairs are formed. The electrons and...
positive holes are collected by the electric field applied, and produce a charge pulse. The charge is proportional to the γ-energy (photoelectric effect) or lower (Compton scattering). After linear amplification and analog-to-digital conversion (ADC), the multi-channel analyzer shows a digital spectrum with photopeak(s) corresponding to the γ-energy/energies, and, at the lower energy side, a Compton continuum.

The characteristics of a Ge detector are described by the performance towards the 1333-keV γ-ray of 60Co: (1) energy resolution, i.e. the full width at half-maximum (fwhm), 2 keV or better; (2) peak to Compton ratio, i.e. the ratio of the photopeak height to the Compton continuum at 1 MeV, typically 40–60; and (3) relative detection efficiency, i.e. relative to a standard (and hence the difference in self-absorption) is exponentially with the count rate. Therefore, the dynamic range of a γ-spectrometer is limited. Different systems are in common use for the dead-time correction: the “live-timer”, which is standard in any spectrometer but not applicable for short-lived isotopes, in contrast to the very simple “pulsar method”, the dead time stabilizer (DTS), and the loss-free counting (LFC) module.

Samples and standards should be measured at the same detection efficiency, which is determined by the source-to-detector geometry, and self-absorption as well. For instrumental analysis of solid samples, it is mostly sufficient to measure samples and standards positioned at exactly the same distance from the detector, with the irradiated side towards the detector. Because of the limited range of CPs in matter, the self-absorption of sample and standard (and hence the difference in self-absorption) is very low or negligible, except for very low γ-energies and high-Z targets. This can be roughly estimated, assuming a point source absorbed by half the range, using mass attenuation coefficients compiled by Hubbell. For radiochemical analysis (section 8.4) the geometry and self-absorption of the sample (solution or precipitate) can be quite different compared to the standard (a “thick” or “thin” foil). The relative (i.e. sample vs standard) detection efficiency has to be determined experimentally. A tracer, preferably the mono-elemental standard or, if not, a radionuclide emitting almost the same γ-energy, is irradiated, measured in the standard geometry, brought into the same chemical and physical form as the sample, and measured again. The chemical form should be as similar as possible with respect to its atomic number, Z.

7.3 Positron Counting

Pure positron emitters have to be measured by their 511-keV annihilation photons, emitted in opposite direction (section 7.1). Although this can be measured by a Ge detector, it is more convenient to use an NaI detector because: (1) the detection efficiency is at least equal, even for small NaI detectors, compared to the state-of-the-art Ge detectors; (2) an NaI detector is much cheaper than a Ge detector; (3) a Ge detector should be cooled with liquid nitrogen but an NaI detector does not need cooling; (4) there is no advantage in obtaining the better energy resolution of the Ge detector, as all positron emitters produce annihilation radiation of the same energy. Therefore, there is no need for a multi-channel analyzer. It is sufficient to use a single-channel analyzer that selects all γ-rays measured in the 0.4–0.6 MeV energy interval.

The signal-to-noise ratio can also be improved by the use of a γ–γ coincidence set-up. Two NaI detectors are used, facing each other, and the β⁺ emitter is placed between them. The annihilation photons are emitted in opposite direction, and can be detected simultaneously in both detectors. A coincidence circuit selects all simultaneous events (typically within 40 ns). The system is very insensitive for all γ-radiation other than annihilation photons, even if present in the sample, for positron sources outside the gap between both detectors and for background radiation or random noise. However, the detection efficiency is lower compared to a single detector, because both annihilation photons should produce a photoelectric effect in each detector. The detection efficiency sharply decreases when the source is moved away from the space between the two detectors. Identical geometry for both sample and standard is still more important than for Ge spectrometry. The relative (sample vs standard) detection efficiency can be determined experimentally, as explained in section 7.1, using a pure positron source like 68Ge/68Ga (t1/2 = 270 days), which is commercially available.

For tuning the set-up (energy range, coincidence time interval) and checking its stability (constant detection efficiency), long-lived positron sources like 22Na (t1/2 = 2.6 years, also a γ-emitter) or 68Ge/68Ga (t1/2 = 270 days) can be used. As annihilation only occurs after the positron slows down, the positron source should be enveloped by an absorber (of any value of Z). An absorber thickness
equal to the positron range for the characteristic maximum energy of the positron emitter (0.2–0.9 g cm\(^{-2}\) for 0.5–2 MeV positrons) is largely sufficient for two reasons: (1) the energy spectrum of the positron emitter is continuous from zero to the characteristic maximum energy; and (2) the projected range (i.e. trajectory projected on the original direction) is much smaller than the linear range (i.e. total path length) for positrons. Indeed, positrons are more deflected when interacting with electrons than with protons. Of course, the annihilation radiation can be absorbed also, therefore a low-Z absorber (plastic, aluminum) is used. The \(\gamma\) absorption of 1-mm aluminum for annihilation photons is 2%.

As for \(\gamma\)-spectrometry, the dynamic range of a \(\gamma-\gamma\) coincidence set-up is limited by "counting losses" or "dead-time". A correction is possible, as given in Equation (30), if the dead-time is known, i.e. the time the set-up needs to process one coincident event.

\[
R_c = \frac{R_m}{1 - R_m \tau}
\]

where \(R_c\) is the count rate corrected for dead-time, \(R_m\) is the measured count rate, and \(\tau\) is the dead-time. This equation is only valid for a non-extensible dead-time, i.e. one that is constant as a function of the count rate. Although this is not the case for a \(\gamma-\gamma\) coincidence set-up, this correction can be applied for counting losses up to 10%, e.g. for \(\tau = 10^{-6}\) min per count and \(R < 10^5\) counts per min. The dead-time can be determined experimentally by repeated measurements of a short-lived radionuclide that is radioisotopically pure and has a well-known half-life. Irradiation of pure graphite or polyethylene with deuterons (<12 MeV) produces the pure positron emitter \(^{13}\)N (Figure 4b) with a half-life of 9.965 ± 0.004 min. Measurements at low count rates, with negligible counting losses, are extrapolated to high count rates \((R_c)\) in Equation (30). The dead-time, \(\tau\), can then be calculated from the measured count rate \(R_m\). Alternatively, the best fitted dead-time can be found with a decay curve analysis program (section 9.2) by trial and error.

8 PROCEDURE

The conceptual and experimental procedures to be followed for trace element determinations in the bulk of a sample and for surface characterization are described as a whole, making reference to the other sections if appropriate. The common part is given in the next section. Finally, a radiochemical separation can improve the detection limit and precision.

8.1 General

The first step is to make an appropriate choice for nuclear reaction and CP energy to avoid possible nuclear, spectral, or matrix interference (section 4). For trace element analysis in the bulk of a sample the matrix is the main component of the sample; for surface characterization the main component is the substrate of the surface layer.

The tools are data for threshold energy, Coulomb barrier, cross-section or TTY (if these are not available then Equation 9 may be used), stopping power or range, and a chart of the nuclides (sections 2 and 3). Examples are given in section 4. Activation curves can be obtained experimentally as described in section 3.4.

To preserve the advantage of CPAA as an "absolute" or "independent" method, no standards may be used that are certified or calibrated by another method. Mono-elemental standards are ideal. Therefore, pure elemental standards (i.e. metals) or a pure compound with exactly known stoichiometry can be used to obtain accurate data for the mass fraction of the analyte element as well as for stopping power. The standard should be stable during irradiation (when heating occurs, as described in section 6.2) in a vacuum. Some organic and hygroscopic compounds cannot be used, not only because the mass fraction of the analyte element increases during irradiation, but more importantly because the stopping power decreases as the hydrogen content decreases. Indeed, the stopping power for hydrogen is 3–5 times higher than for the other elements (Figure 1c). Both phenomena lead to positive errors. Not only should the standard itself be stable during irradiation, but also should the radionuclide formed or any compound of it. Boric acid is a good boron standard for the nuclear reaction \(^{10}\)B(p,\(\alpha\))\(^7\)Be, but not for \(^{10}\)B(p,\(n\))\(^{13}\)C, as the \(^{11}\)C formed volatilizes as carbon dioxide. Boron metal must be used for the latter reaction. To avoid nuclear or spectral interferences the mono-elemental standard should be very pure. Ideally, only activity from the analyte element is found in the \(\gamma\)-spectrum or decay curve.

For irradiation, samples and standards are covered with an \(I\)-monitor foil, a catcher foil for recoil nuclides from the \(I\)-monitor foil, and, if necessary, extra foils for fine tuning the incident energy on sample or standard (section 6.5). Never use the analyte element as an \(I\)-monitor. The thickness of the catcher foil is at least equal to the range of the recoil nuclides. The energy of the recoil nuclides can be calculated exactly, but is always smaller than \(E_a + Q\). So the maximum range can be calculated as described in section 2.3. In practice a few \(\mu\)m is sufficient.

The use of an \(I\)-monitor, a catcher foil and more extra foils slightly reduces the incident energy on the
sample and the standard. Using the definition of stopping power (Equation 1) this can be calculated by using Equation (31).

\[ E_o = E_i - SD \]  

(31)

where \( E_o \) is the outgoing energy, in MeV; \( E_i \) is the incident energy, in MeV; \( S \) is the mass stopping power, in MeV g\(^{-1}\) cm\(^2\); and \( D \) is the mass thickness of the “thin” foil, in g cm\(^{-2}\). For each foil with mass thickness \( D \), the outgoing energy \( E_o \) of the previous foil is the incident energy \( E_i \) of the following foil. For “thin” foils the stopping power is considered constant in the energy interval \( E_o - E_i \). The mass thickness of the foils has to be determined experimentally by weighing and measuring its surface, rather than using its nominal or measured thickness multiplied by a tabulated mass density. For an aluminum foil 10 × 10 cm\(^2\) with a 5-\(\mu\)m nominal thickness, measured with an uncertainty of 0.1 cm and 0.1 mg, the mass thickness yields 1.35 ± 0.03 mg cm\(^{-2}\). The precision on the energy, calculated by Equation (1), yields about 3 keV for \( \alpha \)-particles (\( S \approx 100\) MeV g\(^{-1}\) cm\(^2\)), which is largely sufficient. The precision is much better for protons, deuterons, and helium-3 particles, for foils with an atomic number higher than that of aluminum (i.e., foils with a lower stopping power) or for foils with a mass density higher than aluminum or thicker than 5 \(\mu\)m (i.e., foils with a higher mass).

Irradiations are carried out under vacuum or helium, monitoring the beam intensity as described in sections 6.3 and 6.4. For the standards, shorter irradiation times and/or beam intensities are applied, as the amount of analyte element irradiated is orders of magnitude higher than for the sample. To avoid radioactive contamination from the standards, it is good practice to irradiate the samples prior to the standards.

After irradiation, a waiting time, also called the decay or cooling time, is observed for sample handling, chemical etch (section 8.2) or radiochemical separation (section 8.4).

Measurements of samples and standards are done by \( \gamma \)-spectrometry (section 7.2) or positron counting (section 7.3). \( I \)-monitors by \( \gamma \)-spectrometry. Time management is important to improve signal-to-noise ratio (and thus the detection limit and repeatability) and to avoid or suppress spectral or matrix interferences. For an irradiation time equal to one half-life one obtains half of the activity for an infinite irradiation time (Equation 9). For a waiting time equal to one half-life one obtains half of the activity for no waiting time (Equation 9). Shorter irradiation or waiting times decrease the analyte activity compared with short-lived interfering activities. Longer irradiation or waiting times decrease the analyte activity compared with long-lived interfering activities. The same holds for the measuring time, simply replacing “activity” by “number of counts” (see Equation 34 in section 9.3).

Data handling is described in section 9.

8.2 Trace Elements in the Bulk of a Sample

To obtain high sensitivity, samples and standards are irradiated at an energy slightly above the maximum cross-section, i.e. when the TTY reaches a plateau. For the determination of iron by the \( ^{56}\text{Fe}(p,n)^{56}\text{Co} \) reaction (Figure 3b) the proton energy is about 15–20 MeV. The initial choice is further refined or rejected by considerations of nuclear, spectral and matrix interferences, as explained in section 8.1.

Samples and standards are always “thick” targets (thicker than the range, section 5.2). However, for back-side cooling the thickness should not exceed the range too much (sections 6.2 and 6.3). For massive samples (not powders) interference from the surface can be avoided by chemical etch prior to irradiation, at least if further surface contamination can be avoided until the end of irradiation. It is obvious that chemical contamination after irradiation does not interfere any more. For the determination of carbon, nitrogen or oxygen the sample may be contaminated after chemical etch and prior to irradiation. For example, the alumina layer found in air may interfere with trace oxygen determination in the bulk of pure aluminum. The alumina layer is also activated and the oxygen content is found to be too high. Chemical etch after irradiation is then the method of choice. The activated surface layer will be removed and replaced by an inactive surface layer that will no longer interfere. The thickness to be removed is not determined by the thickness of the oxide layer, but by the range of the recoil nuclides formed from oxygen in the alumina layer. The energy of the recoil nuclides is less than \( E_o + Q \), and its range can be calculated as described in section 2.3. It is good practice to check experimentally the apparent oxygen content compared with the amount removed from the surface layer: a steep decrease followed by a plateau at a few \( \mu \)m. Chemical etch after irradiation reduces the incident energy on the sample, i.e. the sample as it will be measured. Etching the standard is not convenient and may be impossible for powdered standards. A set of two standards is irradiated at two different energies by insertion of additional foil(s) between the recoil foil and the standard. That energy interval should cover the incident energies for all the samples after etch, which is not always very reproducible. Then the standard activity for each individual sample can be obtained by linear interpolation of the set of standards. Energy calculations are done using Equation (31). The mass thickness of the removed surface layer can be obtained by measuring the dimensions of the sample.
and weighing prior to irradiation, rather than etch, and after etch. Linear interpolation is justified if the incident energy is chosen in the plateau of the TTY.

8.3 Surface Characterization of Thin Layers

To obtain high sensitivity, samples and standards are irradiated around the energy for maximum cross-section. If Equation (23) is applied, the cross-section should be nearly constant for the energy interval of the “very thin” standard (sections 5.1 and 5.3). The initial choice is further refined or rejected by considerations of nuclear, spectral and matrix interferences, as explained in section 8.1.

For surface layer characterization samples are always “thin”; the standards can be “thick”, “thin”, or “very thin”, each requiring appropriate standardization, as explained in section 5.3. A “thin” standard does not mean that the standard should be comparable to the sample thickness (the order of magnitude is µm–nm), or that its thickness or composition should be determined by another method. “Thin” standards are typically 10–100 µm thick. Their mass thickness has to be determined experimentally by weighing and measuring the surface, as explained in section 8.2. For a standard that is not available as a foil, a virtual “thin” standard can be used. A set of two “thick” standards is irradiated at two different energies, one without and the other with an additional foil between the recoil foil and the standard. The difference in standard activities is equal to a “thin” standard with a thickness that yields the same energy reduction as the additional foil. The mass thickness of the virtual “thin” standard can be calculated from Equation (32).

\[ D_s = D_f \frac{S_f}{S_s} \]  

where the subscripts s and f refer to the virtual “thin” standard and the foil covering the second “thick” standard, respectively. As the virtual “thin” standard activity results from a small difference in activities, both standards should be measured with good counting statistics. Moreover the virtual “thin” standard should be as thick as possible and still comply with the “nearly constant cross-section” condition.

Heating of the sample during irradiation is described in section 6.2. To avoid activation of the target holder, samples and “thin” standards should be backed by a “thick” thermal conductor, e.g. aluminum for proton irradiation.

8.4 Radiochemical Separation

Instrumental analysis is possible if spectral or matrix interference can be avoided by an appropriate choice of the incident energy and/or the measuring conditions (section 4) and/or time management for irradiation and measurement (section 8.1). If not, the radionuclide B formed from the analyte element A has to be separated radiochemically from an interfering radionuclide D formed from an interfering element C. The latter technique is called radiochemical analysis. This section deals with some major differences between a radiochemical separation and a common chemical separation as used in nonnuclear methods of analysis.

For most CP induced reactions, the atomic number of the radionuclide B is different from that of the analyte element A. This is the case for (p,n), (p,α), (d,n), (d,α), (3He,n), (3He,d), (α,n), and (α,d) reactions, but not for (p,d) and (3He,α) reactions (section 3.4 and Figure 4). The chemical separation to be developed for CPAA is thus different from that for all nonnuclear analytical methods and for some other methods based on activation analysis, such as thermal and fast neutron activation analysis using the (n,γ) or (n,2n) reaction, respectively, and photon activation analysis using the (γ,n) reaction. In principle, it is also not necessary to separate the matrix, but rather the radionuclide(s) formed from the matrix element(s). Again, the atomic number of a radionuclide formed from a matrix element is generally different from that of the matrix element itself. Considering only the chemical separation involved, CPAA is an independent analytical method, not subject to the same systematic errors as other analytical methods. Radiochemical separation has three important advantages over conventional chemical separation:

1. An inactive carrier can be added for the elements to be separated (B and D). This avoids the difficulties of a chemical separation at the trace level.
2. Reagent impurities (or blanks) do not influence the detection limit capabilities of the analytical method.
3. Separations need not be quantitative or even reproducible (see section 8.4.2).

For the choice and development of a radiochemical separation the following points have to be considered:

1. Selectivity of the separation. As pointed out in section 4, the induced matrix activity (D) can be orders of magnitude higher than the activity to be measured (B). It is not possible to resolve such a low activity in the presence of such a high activity, as the dynamic range of the measuring equipment is limited (sections 7.2 and 7.3). Therefore the decontamination factor (the ratio of D before separation to that after separation) should be up to 10^4.
2. Quantitative nature of the separation. Quantitative recovery of B is to be preferred (99% or more).
If the separation is not quantitative and not even reproducible, then determination of the yield for each individual separation is possible. Two approaches can be followed: the addition, before separation, of an accurately known amount of an inactive/active carrier and measurement of the mass/activity of the carrier after separation. It is obvious that the radionuclide added and the analyte radionuclide should be different isotopes of the same element.

3. **Speed of the separation.** To obtain an optimum detection limit, the time needed to perform the whole separation procedure should not exceed a few half-lives of the radionuclide to be measured.

4. **Inactive carrier.** It is not only an advantage, but mostly also a necessity, to add inactive carriers of the elements to be separated. Indeed, if the atomic number of the radionuclide B is different from that of the analyte element A (which is usually the case; see above), this radionuclide B is produced “carrier free”. As the number of radionuclides is given by

\[ N = \frac{A t_{1/2}}{\ln(2)} \]  

(33)

where \( N \) is the number of radionuclides, \( A \) is the activity (in Bq) and \( t_{1/2} \) is the half-life (in s), the amount of substance is \( 10^{-18} \) mol for \( A = 1 \) kBq and \( t_{1/2} = 1 \) day. It is clear that if there is no accidental addition of inactive element B (e.g. as impurity in the matrix or reagents) it is not possible to separate chemically such a low mass.

5. **Detection efficiency of measurement.** To obtain a high sensitivity, the activity should be measured after separation with the highest possible detection efficiency. This is also determined by the geometry (size and distance from the detector) of the source. Separation procedures ending with volumes of solution are less favorable than those ending with a precipitate.

6. **Repeatability of the measurement.** The repeatability of the measurement is determined by the counting statistics and also by the possibility of reproducing measurements with exactly the same detection efficiency. The former is expressed as the relative standard deviation calculated from counting statistics (i.e. \( C^{-1/2} \), where \( C \) is the number of counts measured). For a high detection efficiency, one has to use a small source to detector distance, which is less reproducible geometrically. Obtaining a good repeatability and a high detection efficiency are thus contradictory demands.

7. **Self-absorption of the source.** Self-absorption of the source is in principle no problem, as long as the absorption is identical for all samples and standards, which is mostly the case for instrumental analysis (section 7.2). Self-absorption can be important for low-energy \( \gamma \)-rays or for sources containing components of high atomic number.

8. **Separation of the matrix.** Although in principle not necessary, it may be convenient to separate the (inactive) main matrix components and so reduce the mass of material involved in the separation procedure. The following separation process is then faster, leads to smaller volumes of solution or precipitate and allows further evaporation of a solution to a smaller volume if necessary. As a consequence, the detection efficiency is improved and the self-absorption is lowered substantially or becomes negligible.

The experimental development of a radiochemical separation is supported by the use of radiotracers. The chemical separation is simulated step by step with the addition of radiotracers (and inactive tracers as well) for the element to be separated (B) and for the interfering element (D), in order to check quantitativeness and selectivity. These radiotracers are preferably produced by thermal neutron activation, if such a facility is available, rather than by CP activation. Indeed, production by, for example, a \((p,n)\) reaction yields a radiotracer that has to be separated from the target material, whereas for production by an \((n,y)\) reaction the target material can be used as the inactive carrier. The tracer has to be brought to the same chemical form as the radionuclide to be separated. This is often not possible for the dissolution step preceding the actual separation procedure. So, the choice of the dissolution procedure should guarantee quantitative recovery of the radionuclide to be measured.

For each separation step, three measurements can be made: the initial activity, as a reference; and, after separation, the two fractions in which the major and minor activity are collected. From the measurement of the minor fraction the most precise yield can be calculated. However, it is not always possible to perform all measurements with the same detection efficiency. For a precipitation, for example, the reference measurement is made on the solution before precipitation. After precipitation and filtration, a fraction of the filtrate (equal
in volume to the reference) is taken and the yield for the ion to be precipitated can be calculated very precisely. To check coprecipitation (e.g. of matrix activity) the activity of the precipitate is measured. As the detection efficiency is not comparable with that of the reference measurement, the result has to be considered as an estimate. This is largely sufficient for the purpose of evaluating the selectivity of this separation.

There is no need to apply radiochemical separation to mono-elemental standards. However, standards and samples have to be measured at identical detection efficiency. Therefore the standards are brought into exactly the same geometrical form as the samples after separation. If the last step of a separation is ion chromatography, the standards are dissolved and the total volume is brought exactly to the volume of the eluate. Possible differences in self-absorption have to be considered. The eluate may contain an acid other than the one used to dissolve the standard; the eluate may contain only the added inactive carrier (B), whereas the standard contains a larger amount of the analyte element (A).

9 DATA HANDLING

This section follows chronologically from the previous one. Once the irradiation and measurement data ($\gamma$-spectrum or decay curve) have been collected, they have to be analyzed and the result (i.e. trace element concentration in the bulk of a sample, mass thickness of a surface layer, composition of a surface layer) has to be calculated.

9.1 $\gamma$-Spectrum Analysis

The manufacturers of $\gamma$-spectrometers provide suitable programs to resolve the spectrum, i.e. find the significant peaks and calculate their energy, resolution (i.e. fwhm, and comparison to the detector characteristics), net count area, standard deviation (from counting statistics), and detection limit (in number of counts). Once such data have been obtained, it is not sufficient to search only for the most intense $\gamma$-ray of the analyte radionuclide. The whole spectrum has been analyzed, starting at the high energy side of the spectrum, using databases with $\gamma$-energies and $\gamma$-intensities (number of $\gamma$-rays emitted per 100 disintegrations). It should be noted that the detection efficiency of a $\gamma$-detector is a function of the $\gamma$-energy. For high energy $\gamma$-rays ($E_{\gamma} > 1022$ keV) single and double escape peaks can be observed at an energy equal to $E_{\gamma} - 511$ keV and $E_{\gamma} - 1022$ keV. Two intense $\gamma$-rays, or $\gamma$-rays emitted in cascade, can give rise to sum-peaks. All this can provide useful information concerning the main, minor or trace components in the matrix, which can cause nuclear, spectral and/or matrix interference. Peak broadening is evidence of spectral interference, although no peak broadening does not imply the absence of spectral interference. In case of doubt, decay curve analysis (section 9.2) can be applied to check for spectral interference. All possible reactions on all stable isotopes for an element observed in the spectrum have to be checked, as explained in section 3.4.

Erdtmann and Soyka published a table with $\gamma$-energies and $\gamma$-intensities, ordered by radionuclide as well as energy. This database is also available at the Lund Nuclear Data WWW Service (Lund University, Sweden). The production mode can be specified as “CP reaction”. The database is not updated. The NuDat (Nuclear Data) database is retrievable by, and can be sorted by, radionuclide, half-life, $\gamma$-energy and/or $\gamma$-intensity. The NuDat database at the Lund Nuclear Data WWW Service (Lund University, Sweden) was last updated in January 1996, and will not be updated in the future. In 1999, it is actually the only NuDat base where the production mode can be specified as “CP reaction”. The NNDC databases are updated three to four times a year, and mirrored at IAEA and NEA. The same database is also obtainable as a PC/DOS program: PCNUDAT. The Table of Isotopes (TOI) database is available as a book and a CD-ROM and on the Internet at the Lund Nuclear Data WWW Service (Lund University, Sweden). Both are updated yearly.

9.2 Decay Curve Analysis

Positron counting, followed by decay curve analysis, is only applied when the analyte radionuclide is a pure positron emitter. Unfortunately, all CP induced reactions induce positron emitters, and consequently the decay curve may be very complex. In contrast to $\gamma$-spectra, which may contain hundreds of $\gamma$-rays, the number of components in a decay curve is rather limited (<10). Ideally, a decay curve analysis should answer the questions: (1) how many components are present; (2) what is the half-life of each component; and (3) what is its activity? As most positron emitters are also $\gamma$-emitters, their possible presence in the decay curve can be checked by $\gamma$-spectrometry and avoided by a proper choice of irradiation and measurement conditions. Moreover, the number of pure positron emitters is rather limited and the number and identity of possible components in the decay curve are mostly known. A decay curve analysis that provides an answer to the second question (qualitative analysis) and the third question (quantitative analysis) is acceptable. By weighed linear regression analysis the third question can be answered, the goodness of fit indicating if the initial assumptions about the number and half-life of
the components are correct. The half-life cannot be fitted because the decay curve is a sum of exponential functions, thus the half-life parameter is not linear. Assuming an initial value for the half-life, the problem can be linearized, and so, by iteration, the best half-life can be fitted. Components that are not present can be rejected because their activity is extremely low or negative. Such an algorithm has been developed by Cumming,42 and applied successfully. More recently, Prony’s improved method has been implemented, tested extensively, and compared to Cumming’s method by Schreurs et al.43 This method also answers the first question, but requires data points equidistant in time.

9.3 Quantitation

Standardization is done in a relative way, the sample and standard being irradiated and measured under, principally, identical conditions. As these identical conditions are not fulfilled in practice, some corrections or normalizations are performed first.

The number of counts measured are corrected for:

1. Counting losses (dead-time), according to sections 7.2 and 7.3, and background (for γ-spectrometry this is mainly the Compton continuum of other γ-rays), using a decay curve analysis program.

2. Differences in measurement ($t_w$, $t_m$) conditions (Equation 34), using a decay curve analysis program. The normalized count rate represents the count rate for a decay time zero, i.e. at the end of irradiation. In Equations (22–24) it can replace $A$ for equal detection efficiency of sample and standard.

\[
R = \frac{\lambda C e^{\lambda t_w}}{1 - e^{-\lambda t_m}}
\]  

(34)

where

$R$ = normalized count rate, the number of counts per unit time;

$\lambda = \ln(2)/t_{1/2}$ decay constant (where $t_{1/2} = $ half-life);

$C$ = number of counts measured;

$t_w$ = waiting time;

$t_m$ = measuring time.

3. Differences in irradiation conditions ($I$, $t_i$), corrected for by Equation (18), (22), (23) or (24) (sections 5.2 and 5.3).

4. If applicable, differences in detection efficiency, due to different sample/standard-to-detector geometry and/or self-absorption for sample versus standard (section 7.2).

Finally, difference between the mono-elemental standard and the sample is corrected by Equation (19), (20) or (21) for trace element analysis and Equation (22), (23) or (24) for surface characterization, as explained in sections 5.2 and 5.3. Each individual result can be completed by the standard deviation, calculated from counting statistics, which can be compared to the reproducibility.

For surface characterization, primarily a partial mass thickness is obtained. The total mass thickness can be calculated if the mass fraction (or stoichiometry) is known. The thickness can also be calculated if the mass density is known. Be aware that the mass density can be much lower than the tabulated values, because less dense structures can be deposited, depending on the production mode. The partial mass thickness can also be used to calculate the mass fraction if the total mass thickness is known or if all mass fractions are determined. Also the stoichiometry can be calculated from partial mass thickness data.

10 PERSPECTIVES

10.1 Charged Particle Activation Analysis

During the last two decades CPAA has proved its outstanding capabilities in trace element determinations in solid samples. For the determination of light elements CPAA is still unique. Blondiaux et al. reviewed its applications.44 Recently CPAA has been proposed for surface characterization45 and experimentally validated.46 This method, despite its inherent limitations, is expected to be a reference method, because of its outstanding accuracy, precision and detection limit.

10.2 Charged Particle Activation for the Development of Other Analytical Methods

In addition to CPAA, the production of carrier-free (section 8.4) radionuclides by charged particle activation (CPA) can be a magnificent tool in the development of other analytical methods. A radioactive tracer is a molecule labeled with a radionuclide. A carrier-free radionuclide or tracer is one with a high specific activity, i.e. activity per mass unit. At very low concentrations some analytical methods require preconcentration or chemical separation prior to measurement. These methods can be developed using these tracers, because the extremely low amount of analyte is almost unchanged. The tracer experiments can be performed at the same concentration levels as the final analyses. The activity levels required are very low, and do not present a significant risk. Using rather short-lived radionuclides, there is no waste problem either. An example47,48 is the determination of platinum by inductively coupled plasma mass spectrometry (ICPMS), using $^{191}$Pt.

Cyclic activation analysis (CAA) is a method of activation analysis for elemental analysis, in which a sample is irradiated, decayed, counted, and then irradiated again. This process is repeated for a number of cycles, and the spectra from each counting are summed together to give one final total spectrum. By this process, the counts of a short-lived nuclide of interest are considerably increased, and the analytical sensitivity of elements is significantly improved. The most commonly used CAA is the cyclic neutron activation analysis (CNAA) by irradiation with the thermal, epithermal, and fast neutrons produced from nuclear reactor, accelerator, and isotopic neutron source. The nuclear reactor can supply a much high neutron flux and is most often used for this purpose. At least 20 elements produced short-lived nuclides (half-life <100 s) by thermal neutron bombardment, and more than 10 elements produced nuclides with half-life of 100–600 s. These can be determined by thermal and epithermal neutron CAA. This technique has been widely applied in biological, environmental, geological, and industrial studies, and most often measured elements include Se, F, Pb, Hf, Sc, O, Ag, and Rh.

The advantages of CAA, as compared with conventional activation analysis, include significant improvement in the detection limit, analytical precision, and accuracy for the elements by using short-lived nuclides; short experimental time and increased analytical number of samples per unit time; capability of estimation or confirmation of the half-life of the short-lived nuclide; and determination of the degree of homogeneity of a sample. However, the application of CAA is limited by the number of elements determined, because only some of the elements determined by conventional activation analysis can be determined by this method. In addition, dead time and pileup are serious problems in CAA and must be corrected. The principle, selection of optimal experiment conditions, detection limit, analytical precision of CAA, as well as the dead time and pileup corrections are discussed in this article. Some applications of this method are highlighted.

1 INTRODUCTION

Activation analysis has been well documented as a powerful technique for elemental analysis (see Instrumental Neutron Activation Analysis, Charged Particle Activation Analysis). Its high sensitivity and accuracy, simultaneous multielement analytical capability, and matrix-free and nondestructive analysis make it wide applicable in a variety of research fields such as biological, environmental, geological, industrial, archeological, and forensic studies. Of all kinds of activation analyses, reactor neutron activation has been the mostly used, and as many as 70 elements can be easily determined. However, for many elements, an analytical period from days to weeks is needed because the nuclides detected, which are produced by reaction of their stable isotope with neutron, have longer half-life, such as $^{75}$Se (120 days), $^{46}$Sc (84 days), $^{110m}$Ag (250 days), and $^{181}$Hf (45 days). To attain the required sensitivity, a long-time irradiation, delay, and counting are necessary. This reduces its competitive capability to other analytical techniques, such as inductively coupled plasma mass spectrometry (ICP–MS). The use of the short-lived nuclides of element in preference to their longer-lived activation products can significantly reduce the total experimental time, which in turn can reduce the analytical period and increase the number of samples measured per day, and make activation analysis more cost-effective and competitive. On the other hand, several elements can be determined.

Encyclopedia of Analytical Chemistry R.A. Meyers (Ed.) Copyright © 2008 John Wiley & Sons Ltd
by neutron activation analysis (NAA) only through the measurement of short-lived nuclide, such as $^{20}\text{F}$ (11 s), $^{16}\text{O}$ (27 s), and $^{207}\text{m}\text{Pb}$ (0.8 s). Therefore, NAA using short-lived nuclides has been given more attention.

The saturation activation of short-lived radionuclides is reached quickly on irradiation, and there is no further increase in activity with time. Similarly, the counting is also limited by half-life since the activity of a short-lived radionuclide decays very quickly, and further counting cannot accumulate any more counts of radionuclides of interest; on the contrary, it increases the background derived from long-lived interfering nuclides. In addition, owing to the short half-life, the number of radioactive nuclei ($N^*$) formed in saturation is small ($N^* = N\sigma\Phi/\lambda = N\sigma\Phi t_{1/2}/\ln 2$, where $N$ is the number of target nuclei, $\sigma$ is the activation cross section, $\Phi$ is the neutron flux, $\lambda$ is the decay constant, and $t_{1/2}$ the half-life of the formed radioactive nuclide). Consequently, the counting has a large statistical error, and both the analytical accuracy and detection limit are unsatisfied. It is possible, however, to overcome this by reirradiating sample and counting it again, once the initial activity has been decayed away.

The number of counts of the nuclide of interest can be significantly increased by repeating this process of irradiation-decay-counting-decay and irradiation again for a number of cycles, i.e. cyclic activation, and summing the spectra from each counting to give a final spectrum. By this CAA, the sensitivity, precision, and accuracy will be considerably improved.

The history of CAA can be traced back to the beginning of 1960s. In 1960 and 1961, Anders first reported a technique where a sample is cycled between the irradiating source and the radiation detector, in order to improve both the sensitivity and statistical certainty of the elemental analysis. In his experiment, he repeatedly irradiated the sample with neutrons from a Be target of a 2-MeV Van de Graff accelerator and counted on a NaI(Tl) detector for two consecutive periods of equal length. By subtracting the spectra acquired from each other, the resulting $\gamma$-ray difference spectrum represented the contribution from only very short-lived nuclides and suppressed the contribution of longer-lived components in the $\gamma$-spectra of the activated sample. The method was documented by determining fluorine using faster neutron reaction of $^{19}\text{F}(n, \alpha)^{16}\text{N}$, and Se, Ag, Hf, F, and O by thermal neutron $(n, \gamma)$ reactions. Preliminary investigation indicated the usefulness of the technique for the determination of 18 elements, such as O, F, Na, Sc, Ge, Se, Br, Y, Rb, Rh, Ag, In, Er, Hf, W, Yb, Ir, and Au. However, the term cyclic activation analysis is not mentioned in this article. In 1966, Caldwell et al. suggested the use of a similar technique as part of a combination neutron experiment for remote elemental analysis. The term cyclic activation analysis was first used by Givens et al. in 1968, when they measured $^{16}\text{N}$ and $^{24}\text{mNa}$ using a technique similar to that of Anders. However, the irradiating source, rather than the sample, was cycled electronically. Using this facility, the nuclides with half-life down to a few milliseconds, such as $^{24}\text{mNa}(20\text{ ms})$, can be utilized for analytical purposes. In 1969, Tani et al. used a similar experimental facility to observe the $\gamma$-spectra of $^{205}\text{Pb}$ ($\sim 4\text{ ms}$) and $^{207}\text{mPb}$ (800 ms).

In order to obtain the high sensitivity required while using CNA as a useful trace element analysis technique, Ozek and Spyrou et al. in 1973, first used nuclear reactor as a neutron source to supply a neutron flux more than three orders of magnitude higher than other sources used by the earlier workers, such as an accelerator and isotope sources for CNAA. They published their results on the measurement of lead through $^{207}\text{mPb}$ in environmental samples. Since 1970s, many facilities for CAA have been set up, and methodology and application studies were carried out. This article is an updated version of the previous one published in the first edition of this book in 2000.

2 THEORY

2.1 Equation of Cyclic Activation Analysis

The principle of CAA has been described by Given et al. and Spyrou. In this method, the sample is irradiated for a short period of time, and after a delay period from the end of irradiation, the radiation emitted is counted for a short period of time, then the sample is irradiated again and the entire process is repeated for a number of cycles (Figure 1). The detected radiations at each counting period are summed and finally a total cumulative detector response is obtained. The cycle period $T$ is given by Equation (1):

$$T = t_i + t_d + t_c + t_w$$

where $t_i$ is the time of irradiation, $t_d$ is the delay time, i.e. the time between the end of irradiation and the start of counting, which is usually the time required to transfer the sample from the irradiation position to the counting station, or to transfer the irradiation source to the sample station. $t_c$ is the counting time, and $t_w$ is the waiting time, i.e. the time between the end of counting and the start of the next irradiation.

The detector response (or the number of counts) for the first cycle is given by Equation (2):

$$D_1 = \frac{N\sigma\Phi I_0}{\lambda}(1 - e^{-\lambda t_i})e^{-\lambda t_d}(1 - e^{-\lambda t_c})$$
where the definitions of $\sigma$, $\Phi$, and $\lambda$ are the same as above, $I$ is the intensity of the radiation of interest, and $\varepsilon$ is the counting efficiency of the detector.

In the second counting period, the detector response is the same number of counts due to the second irradiation in addition to what was left from the first irradiation, expressed by Equation (3):

$$D_2 = D_1 + D_1 e^{-\lambda T} = D_1 (1 + e^{-\lambda T}) \quad (3)$$

Similarly, for the $n$th cycle, which can be expressed by Equation (4)

$$D_n = D_1 (1 + e^{-\lambda T} + e^{-2\lambda T} + e^{-3\lambda T} + \cdots + e^{-(n-1)\lambda T}) \quad (4)$$

Then the total cumulative detector response in all $n$ cycles is given by Equation (5):

$$D_c = \sum_{i=1}^{n} D_i = D_1 \left[ \frac{1 - e^{-\lambda T}}{1 - e^{-\lambda T}} \right]$$

$$= \frac{N \Phi \sigma I \varepsilon}{\lambda} \left[ \frac{n}{1 - e^{-\lambda T}} - \frac{e^{-\lambda T}}{(1 - e^{-\lambda T})^2} \right]$$

$$= (1 - e^{-\lambda T})e^{-\lambda t_d}(1 - e^{-\lambda t_c}) \quad (5)$$

Equation (5) gives the basic relationship for CAA.

2.2 Selection of Time Parameters

The detector response may be maximized by a proper selection of the parameters in Equation (5). For a given total experiment time, $T_i$ ($T_i = nT = mt_i/2$), the maximal value of $D_c$ occurs when $t_d = t_w = 0$ and $t_i = t_c$. However, the fact is that $t_d$ and $t_w$ are not zero and their values ultimately depend on the transfer system used. When the transfer is done manually, the transfer time can be relatively long in the value of 10 s to 1 min; in this case, the method sometimes is referred to as pseudocyclic activation analysis (PCAA). In some fast transfer system, where the transfer is completed electronically and through computer control, the transfer time is of the order of 0.1 s and less. The transfer time can be made very small when there is no physical transfer of the sample but a pulsed irradiation is used, which was suggested as the “real” CAA. For the following discussion, unless otherwise stated, it is assumed that $t_d = t_w = 0$ and $t_i = t_c$.

Figure 2 shows the variation of detector response for the nuclides of interest with the total experimental time $(T_i = mt_i/2 = nT)$ in conventional and cyclic case with different cyclic numbers. It is clear that below a certain experimental time, conventional activation is to be preferred to cyclic activation, and the cross over point of curves between conventional and cyclic activation shifts to longer experimental time with an increasing number of cycles. After the cross over point, cyclic activation has a higher detector response than that of conventional one-shot irradiation. For a certain total experimental time, such as $T_i = 10t_i/2$, the cumulative detector response increases with increasing number of cycles in the beginning, and there is an optimum cyclic number, after which the detector response does not increase and slowly decreases (Figure 3). In addition, for conventional single-shot activation analysis, the detector response increases quickly

![Figure 1](image1.png)  
**Figure 1** Time parameters of CAA and the variation of the activity of nuclide with time and cyclic number.

![Figure 2](image2.png)  
**Figure 2** Variation of the conventional and cumulative signal with total experiment time, $t_d = t_w = 0$, $t_i = t_c$ and $n$ is the number of cycles.
with increase in the total experiment time in the beginning and 95% of saturation activity is obtained before 5T_{1/2}, following which a further increase in the total experiment time becomes insignificant (Figure 2). However, for CAA, this time point becomes longer. For n = 4, 95% of saturation activity is obtained after 15T_{1/2}, and for n = 12, after a total experiment time of 50T_{1/2}, the activity still increases with the increase in total experiment time.

However in CAA, the radionuclides produced from elements in the matrix, which has a longer half-life than the nuclide of interest, will decay slowly between irradiations and therefore the underlying background will increase through successive irradiation. Consequently, the detection of an element does not depend solely on the signal from the nuclide of interest, but also depends on the background contribution from the matrix elements.

The purpose of CAA is to improve the analytical precision and detection limit for the elements of interest. The analytical precision is usually expressed by relative standard deviation of a signal S measured above a background B (Equation 6):

\[ \delta = \frac{\sqrt{S + 2B}}{S} \]  

(6)

For the cumulative spectrum of n cycles, it is expressed as Equation (7):

\[ \delta_n = \frac{\sqrt{(sD_c + 2bD_c)}}{sD_c} \]  

(7)

where \( sD_c \) is the cumulative detector response for the nuclide of interest, \( bD_c \) is the cumulative detector response for the nuclide making the major background contribution to the signal from the nuclide of interest.

The detection limit \( L_d \) is usually given by Equation (8):

\[ L_d = 2\sqrt{B} \]  

(counts)

or \[ L_d = \frac{2\sqrt{B}}{S/m} = \frac{2m\sqrt{B}}{S} \]  

(8)

where \( S/m \) is the counts per unit mass element of interest.

For CAA with n cycles, the detection limit is given by Equation (9):

\[ L_d = \frac{2\sqrt{bD_c}}{sD_c/m} = \frac{2m\sqrt{bD_c}}{sD_c} \]  

(9)

Therefore, \( \frac{\sqrt{bD_c}}{sD_c} \) or \( \frac{\sqrt{D_c}}{\sqrt{bD_c}} \) and \( \frac{\sqrt{sD_c + 2bD_c}}{D_c} \) or \( \frac{\sqrt{D_c + 2D_c}}{D_c} \), not the detector response for the nuclide of interest, must be optimized, when the most suitable cyclic timing parameters are chosen for a nuclide.

In Figures 4 and 5, the signal-to-noise ratio \( \frac{\sqrt{D_c}}{\sqrt{bD_c}} \), and the ratio of signal to the square root of sum of \( sD_c \) and \( 2bD_c \), \( \frac{\sqrt{sD_c + 2bD_c}}{D_c} \), are plotted versus total experiment time \( mt_{1/2} \) for comparison of cyclic with conventional activation analysis. In this case, for illustrative purpose, assuming that only one long-lived nuclide with a half-life \( T_{1/2} \) of 10 times half-life of nuclide of interest \( T_{1/2} = 10t_{1/2} \) is considered to contribute to the underlying background of the signal. It can be seen that the background plays a significant role in emphasizing the difference between conventional and cyclic cases. With increase in the total experiment time, \( \frac{\sqrt{D_c}}{\sqrt{bD_c}} \) and \( \frac{\sqrt{sD_c + 2bD_c}}{D_c} \) have a maximum and this maximum shift to a longer experimental time with increasing number of cycles (Figures 4 and 5). Comparing with Figure 2, the cross over point between conventional and cyclic activation in Figure 4 is shifted to a lower value of \( m \),

Figure 3 Variation of signal and signal-to-noise ratio \( \frac{\sqrt{D_c}}{\sqrt{bD_c}} \) for cyclic and conventional activation with the number of cycles. Here, the underlying background to signal from the nuclide of interest provided by the activity of nuclide with half-life equal to 10 times half-life of nuclide of interest \( (T_{1/2} = 10t_{1/2}) \).

Figure 4 Variation of signal-to-noise ratio \( \frac{\sqrt{D_c}}{\sqrt{bD_c}} \) for cyclic and conventional activation with the total experiment time \( (T_{1/2} = 10t_{1/2}) \).
i.e. cyclic activation becomes advantageous for shorter total experiment time than the case just considering the detector response.

Figure 6 shows the variation of signal-to-noise with the total experimental time (number of cycle) under a certain cycle period \( (T = 2t_{1/2}) \). It is clear that in this case, signal-to-noise ratio increases always with increasing total experiment time.

To obtain a better cyclic advantage factor over conventional activation, it is obvious that one must increase the total experiment time \( (nt_{1/2}) \). Choice of the best total experiment time for cyclic activation is therefore a compromise between the time available for sample analysis and the detection limit to be achieved. Whenever the total experiment time is chosen, the number of cycles \( (n) \) or cycle period, \( P = T/n \), has to be decided. In Figure 3, the variation of the signal \( (D_c) \) and the signal-to-noise ratio \( (D_c/\sqrt{bD_c}) \) were plotted as a function of the number of cycles \( (n = T/T) \). It can be seen that after a certain cycle, \( D_c \) and \( D_c/\sqrt{bD_c} \) increase very slowly, and with further increase in the number of cycles these become insignificant. After a maximum occurs, \( D_c \) decrease slowly. For example, if \( T = 10t_{1/2} \) and \( T_{1/2} = 10t_{1/2} \), 95% of saturation activity of nuclides can be obtained after four cycles and 95% of a maximum of \( (D_c/\sqrt{bD_c}) \) after eight cycles. In addition, in order to maximize signal \( (D_c) \), the optimal number of cycles is always smaller than that required for maximizing the signal-to-noise ratio \( (D_c/\sqrt{bD_c}) \), and it also increases with the increase in the half-life of the background for the same total experiment time. However, it becomes less pronounced for the half-life of the background more than 100\( t_{1/2} \).

Spyrou et al.\(^{(18)}\) and Spyrou and Kerr\(^{(23)}\) investigated the effect of the transfer time \( (t_d \text{ and } t_w) \) on \( (D_c) \) and \( (D_c/\sqrt{bD_c}) \). They found that the cross over point between cyclic and conventional activation was shifted to a longer experiment time with increasing transfer time. It means that CAA becomes more preferable to the conventional method with decreasing transfer time, and the transfer time is an important factor effecting the detection limit and precision.

In real situation, many long-lived nuclides from matrix elements, not just one, will contribute to the underlying background of the peak of the nuclide of interest after activation. For calculating these contributions and optimizing the parameters of cyclic activation, many computer programs have been developed.\(^{(24–26)}\) In Tout and Chatt’s program,\(^{(25)}\) by entering total experiment time, transfer time \( (t_d \text{ and } t_w) \), the mass of sample and relevant nuclear data of matrix elements contributing to the background activity, as well as the half-life of the nuclide of interest, \( D_c/\sqrt{bD_c} \) can be calculated for individual matrix elements and the total background. The optimal irradiation and counting time (or number of cycles) and its ranges were finally given for maximum and 95% of maximum of \( D_c/\sqrt{bD_c} \). Their results indicated that a single value of \( t_i \) and \( t_c \) can be used to produce results close to the maximal \( D_c/\sqrt{bD_c} \) for nuclides with a large range of half-lives, i.e. for a total experiment time of 5 min, \( t_i = t_o = 6–7 \text{ s} \) will produce values of more than 90% of maximal \( D_c/\sqrt{bD_c} \) for nuclides with half-lives in the ranges 3–22 s. This means that a number of short-lived nuclides can be measured at close to their best detection limits by using only one set of CAA.

In Al-Mugrabi and Spyrou’s program,\(^{(26)}\) besides the contribution from the photopeaks of nuclides produced by matrix elements to the background, the Compton continuum, single and double escape peaks, and bremsstrahlung were also considered. By entering the information in Tout and Chatt’s program, as well as by entering neutron flux, mass of sample and nuclear data of nuclide of interest and detector parameters, not only the optimized activation conditions were produced but also simulated \( \gamma \)-spectrum, detection limits, and precision for the elements of interest were presented.
Figure 7 shows the experimentally measured variation of detection limit and analytical precision of CNAA for Se in human hair, with cyclic period of $T = t_i + t_d + t_w = 30 + 3 + 30 + 3 = 66$ s. It can be clearly seen that CNAA can significantly improve the detection limit and precision.

### 2.3 Estimation or Confirmation of the Half-life of Nuclide

Another function of CAA, estimation and confirmation of the half-life of nuclide by using the data obtained during the CAA, was suggested by Spyrou.\(^{18,27,28}\)

For large $n$, $(1 - e^{-n\lambda T})$ tends to unity, Equation (5) can be reduced as

$$D_c = D_1 \frac{n}{(1 - e^{-\lambda T})} - \frac{D_1 e^{-\lambda T}}{(1 - e^{-\lambda T})^2}$$

(10)

where $D_c$ is a linear function of $n$ with all other parameters constant. Plotting $D_c$ as a function of $n$, the slope of the line is given by Equation (11):

$$a = \frac{D_1}{(1 - e^{-\lambda T})}$$

(11)

and the intercept by Equation (12):

$$b = \frac{D_1 e^{-\lambda T}}{(1 - e^{-\lambda T})^2}$$

(12)

The half-life of the nuclide measured can be calculated by Equation (13):

$$t_{1/2} = \frac{T \ln 2}{\ln (1 - a/b)}$$

(13)

For this purpose, it is necessary to store the spectra of each individual cycle instead of using the accumulative spectrum.

### 2.4 Dead Time and Pileup Correction

CAA is usually employed for the determination of short-lived nuclides in a matrix of long-lived activation products. The activity of a sample not only changes considerably during a counting period owing to short-lived nuclide decay but also increases from cycle to cycle because of the matrix activity owing to the accumulation of longer-lived products. Consequently, a rapidly changing dead time is encountered in a counting period. The basic Equation (14) for dead time correction was given by Schonfeld\(^{29}\):

$$C = \int_0^{t_i} A_0 e^{-\lambda t} [1 - DT(t)] \, dt$$

(14)

where $C$ is the actual acquired net counts in photopeak of interest, $A_0$ is the true initial photopeak count rate, and $DT(t)$ is the fractional analyzer dead time at time $t$. In order to implement this correction, the variation of fractional dead time during the counting period must be known. By the least square fitting of the experimental data, Egan et al.\(^{30}\) found that $DT(t)$ is an exponential function of $t$, and it can be expressed by Equation (15):

$$DT(t) = B + Ce^{-kt}$$

(15)

where $B, C,$ and $k$ are constants. Hence, a correction factor ($f$) for dead time in a counting period can be obtained using Equation (16).

$$f = \frac{\int_0^{t_i} A_0 e^{-\lambda T} (1 - B - Ce^{-kt}) \, dt}{\int_0^{t_i} A_0 e^{-\lambda T} (1 - B - Ce^{-kt}) \, dt}$$

(16)

For cyclic activation with $n$ cycles, the correction factor ($F_n$) can be expressed by Equation (17):

$$F_n = \frac{\sum_{n=1}^n \int_0^{t_i} A_0 e^{-\lambda T} \, dt}{\sum_{n=1}^n \int_0^{t_i} A_0 e^{-\lambda T} (1 - B - Ce^{-kt}) \, dt}$$

(17)

$DT(t)$ not only varies with $t$ in a counting period but also differs from one cycle to another. $F_n$ is also a function of $n$.

It was observed that the correction factor for the dead time, $f$, is approximately equal to the ratio of clock time...
to live time obtained from the multichannel analyzer clock data in each counting period.\(^{30}\) Hence, it is usually used to correct for dead time after each cycle. In this case, it is important to store the \(\gamma\)-spectra of each cycle period and correct the counts of interest nuclide for dead time before summation of individual spectrum.

With increasing analyzer dead time, the pulse pileup loss (also called summing effects or coincidence losses) will become more serious. It can be overcome satisfactorily by introducing a pulser with constant frequency into the system.\(^{30}\) The ratio of the areas under the pulser peaks, after dead time correction, was measured and the pileup correction factor was defined as \(F_p\) (Equation 18):

\[
F_p = \frac{\text{Pulser peak area (at } \sim 0\% \text{ dead time)}}{\text{Pulser peak area (at sample dead time)}} \quad (18)
\]

However, pileup correction, unlike dead time, is implemented on the cumulative spectrum.

Wyttenbach\(^{31}\) suggested another way to correct the pileup loss by using the real time (cock time), \(\tau_c\), and the live time of the measurement, \(T_c\) (Equation 19):

\[
F_p = \frac{P}{P_0} = 1 - \frac{2\tau}{\nu} \left( \frac{\tau}{T_c} - 1 \right) \quad (19)
\]

where \(P_0\) is the true photopeak count rate without coincidence losses, \(P\) is the actual photopeak count rate including pileup, \(\nu\) is a constant of the detector system, and \(\tau/\nu\) can be measured by plotting \(P/P_0\) versus \(\tau_c/T_c\) and subsequently be used to correct other spectra. However, it should be considered that actually \(\tau\) depends on the energy of the \(\gamma\) ray measured.\(^{32}\) In addition, the use of a loss-free counting system with pileup rejection will avoid this problem.\(^{33}\)

### 2.5 Cumulative Activation Analysis

Guinn\(^{34}\) suggested another method similar to CAA, which is based on the irradiation and counting of a number of replicates of the same sample and the individual spectra are summed to give one total spectrum. As the activity derived from activated matrix elements is the same for each cycle, the background count and the dead time in each cycle does not increase with the increasing number of replicates. Hence, this will lead to a better precision and detection limit than that of normal CAA for short-lived nuclides. The main advantage of this method is that a large representative sample can be measured even in the case of material, which activates to form high radioactive products.

By this method, Parry\(^{35,36}\) measured rhodium, silver, and gold in some geological samples and reference materials and found that the detection limit was improved by a factor of 4.4–4.7 using 20 replicates in accordance with the theoretical factor of \(n^{1/2}\). The main disadvantage of this method is the long time required for the preparation of \(n\) samples for each material to be analyzed, and the application is limited by the amount of samples available.

For overcoming the relatively high error resulted from inhomogeneity of sample, Farooshi et al.\(^{37}\) suggested combining this technique (called mass fraction) with normal CAA to analyze fluorine in diet sample. In addition to good precision, a lower detection was also obtained.

### 3 CLASSIFICATION AND FACILITIES OF CYCLIC ACTIVATION ANALYSIS

According to source-target-detector system, Spyrou\(^{38}\) classified CAA in the following five types:

1. An “external” beam of incident radiation, which can be mechanically chopped or electronically pulsed with stationary target, such as pulsed neutron source (or called neutron generator) as used by Givens et al.,\(^{4,5}\) in which the waiting time can be as short as 0.5 ms. This type of CAA was termed real CAA. However, the radiation flux supplied in this system is usually low, i.e. the total 4\(\pi\) neutron flux is only \(1.16 \times 10^{11}\) n s\(^{-1}\) in the facility used by Given et al.\(^{4,5}\)

2. An “external” beam providing a continuous source of incident radiation, with the target moving into and out of the beam either linearly or by rotation. The typical source of this type of CAA is neutron source produced by an accelerator with which, in addition to fast neutron, thermal neutrons can be supplied. Further, the energy of neutron can also be chosen, which is very useful to avoid some interfering nuclear reactions. The neutron flux supplied usually ranges from \(10^6\) to \(5 \times 10^{11}\) n cm\(^{-2}\) s\(^{-1}\). Most fast neutron CAA has been carried out in this kind of facility.\(^{1,2,14,38,39}\)

3. An “enclosed” beam where the target is made to oscillate either cyclically or linearly into and out of the beam. The main radiation source in this type of CAA is the core of reactor. Not only can a high neutron flux (\(10^{11}–10^{12}\) n cm\(^{-2}\) s\(^{-1}\)) be used but also the thermal, epithermal, and fast neutron activation can be carried out. By detection of \(\gamma\) ray by coaxial HpGe (or Ge(Li)) and low-energy photon detector and delay neutron by neutron detector, most elements can be determined with a high accuracy and a good detection limit. Most CAA work has been implemented using this type of system.\(^{7–13,18–20,23,25,27,30,37}\) Figure 8 shows a schematic diagram of this system. Similar facilities
have been set up for CNAA in such institutions as University of London Reactor Center, UK,\(^{(10)}\) Dalhousie University, Canada,\(^{(9)}\) MNSR, China Institute of Atomic Energy,\(^{(13)}\) MNSR, Syria,\(^{(40)}\) MNSR, Shenzhen University, China (Personal communication), JRRS-SM, Japan Atomic Energy Research Institute, Japan,\(^{(41)}\) Atominstitut, Vienna,\(^{(12)}\) University of Missouri, USA.\(^{(39)}\)

4. The case of an isotopic source, where the target remains stationary but the source is made to oscillate to and from the target position. The most commonly used isotope neutron source is Am–Be and \(^{252}\)Cf neutron source.\(^{(42,43)}\) A useful application of this system is in vivo NAA. The neutron flux supplied in this system is only \(10^4 - 10^6\) n cm\(^{-2}\) s\(^{-1}\), and the detection limit is therefore high.

5. A primary source creating a secondary source, which in turn provides the irradiation beam for the target. An example of this case is the neutron interrogation system described by Mardani,\(^{(44)}\) where a neutron beam is made to impinge on nuclear fuel, which on fission produces neutrons that act as the secondary source for the activation of a continuously circulating fluid (freon) containing fluorine. The reaction \(^{19}\)F(n, \(\alpha\))\(^{16}\)N was used to determine the amount of fissile material in the fuel element by cyclic measurement of \(^{16}\)N (7.2 s).

In all types of CAA, most work has been carried out using CNAA. Depending on the neutron source used, CNAA can be classified as reactor, neutrons produced by accelerator and neutron generator, and isotopic source CNAA. On the basis of the energy of neutron, it can be classified as thermal, epithermal, and fast neutron CAA; on the basis of the radiation emitted from the activated nuclide, it can be classified as \(\gamma\) ray and delay neutron CAA. Table 1 lists the elements that can be determined using different types of CNAA. The nuclear parameters of elements probably detected by cyclic thermal NAA and cyclic fast neutron activation analysis (FNAA) using their short-lived nuclides \((T_{1/2} < 100\text{ s})\) are listed in Tables 2 and 3, respectively. In addition to the elements listed in Tables 2 and 3, some elements with half-lives of medium \(T_{1/2} > 100\text{ s}\), such as Al, Mg, Ca, V, Cu, S, Mn, Na, Cl, K, Ti, Co, Br, I, In, Sr, U, and Th, may occur in the cumulative \(\gamma\)-spectrum or can be further counted a few minutes after the last cycle. These can, therefore, also be determined simultaneously.

4 APPLICATION OF CYCLIC ACTIVATION ANALYSIS

CAA was first suggested for the analysis of geological materials,\(^{(3–5)}\) but with its development and maturity, this technique has been used in every field of elemental analysis, and there are numerous articles dealing with the application of CAA. Some main applications are discussed below.

4.1 Determination of Se, F, and O in Biological Materials

Selenium is known as a biological essential trace element, its concentration in normal biological tissues is lower than \(1.0\mu\text{g g}^{-1}\), and a sensitive analytical technique is
required for its quantitative determination. NAA is a sensitive method for the determination of Se. In most cases, analysis is performed by measuring $^{75}$Se, which has a longer half-life (120 days), and therefore needs a relatively long analytical period (weeks to months). The uses of short-lived isotope $^{77m}$Se can considerably reduce the analytical time to a few minutes and thus the analytical expense. However, the detection limit and analytical precision are usually not good enough by conventional single-shot irradiation due to quick decay of $^{77m}$Se. CNAA satisfactorily solved this problem, and therefore has been widely used for this purpose.$^{(13,19,20,30)}$ Figure 9 shows $\gamma$-spectra of $^{77m}$Se in biological sample acquired by conventional single-shot NAA and CNAA. Although the background is increased, the signal of $^{77m}$Se and the signal-to-background ratio are significantly improved by CNAA. Shi et al.$^{(48)}$ compared the conventional NAA with CNAA for the determination of Se in different food samples. In general, the detection limit of Se by measuring $^{77m}$Se ($t_i : t_d : t_c = 30 s : 10 s : 30 s$) is better than that by measuring $^{75}$Se ($t_i : t_d : t_c = 17 h : 16 days : 12 h$) using the same neutron flux by a factor of 1.5, and the detection limit using CNAA with three cycles is two times better than the single-shot NAA.

Figure 7 shows the detection limit and analytical precision for Se in human hair by conventional and cyclic NAA, respectively. It can be clearly seen that both detection limit and analytical precision were significantly improved by CNAA. Considering the interference from $^{38m}$Cl ($t_{1/2} = 0.715 s$), the optimal time parameters of CNAA of biological samples for Se given by Egan et al.$^{(30)}$ are $t_i = 19.5 s, t_d = 3 s, t_c = 18 s$, and $t_w = 1 s$. Under these conditions, the samples with Se concentrations as low as 10 ng g$^{-1}$ have been analyzed,$^{(49)}$ and usually 10 samples can be treated in 1 h. CNAA has also been used for the determination of Se in urine$^{(50)}$ and nail$^{(51)}$ and as low as 1.8 ng g$^{-1}$ Se in urine samples has been measured.$^{(50)}$

In MNSR, China Institute of Atomic Energy, more than 2000 varieties of biological samples, such as human and animal tissues and body fluids, diet, and vegetation, have been analyzed for Se using this method in the last few years.

Fluorine is another human essential trace element and a bone seeker. Dental caries and osteoporosis were thought to be related to the intake of F and

the concentration in the tissues. Only one isotope, \(^{20}\text{F}\), can be used for its determination by NAA. Owing to very short half-life of \(^{20}\text{F}\) (11.2 s), CNAA was therefore widely used for its determination.\(^{(9,11,37,52)}\) Under the conditions of \(t_i = t_c = 10 \text{ s}\) and \(t_d = t_w = 2 \text{ s}\), a detection limit of 1–10 \(\mu\)g g\(^{-1}\) for diet sample can be obtained by 14 cycles.\(^{(37)}\) For the same condition, the detection limit of \(^{20}\text{F}\) in bone was reported to be 52 \(\mu\)g g\(^{-1}\)\(^{(52)}\); this is mainly attributed to the high background under \(^{20}\text{F}\) \(\gamma\)-ray peak (1633 keV), which is due to high \(^{28}\text{Al}\) signal (1779 keV) in the spectra for bone samples. Since the reactions \(^{23}\text{Na}(n, \alpha)\(^{20}\text{F}\) and \(^{20}\text{Ne}(n, p)\(^{20}\text{F}\) can also produce \(^{20}\text{F}\), and the concentration of Na is much high in biological samples, the sodium interference must be corrected for. In addition, this interference can be significantly reduced using well-thermalized neutrons, such as irradiating in a thermal neutron irradiation facility in research reactors. Fluorine was actually the first element to be determined in CAA.\(^{(1,2)}\) In addition to Se and F, De Silva and Chatt\(^{(20)}\) also determined other elements, such as Rb, Ag, Sc, Al, Ca, Cl, Cu, K, Mg, Na, V, and I, in biological samples simultaneously by using one analytical condition; Cheng et al.\(^{(45)}\) has also determined Ag and Sc in nail samples using CNAA.

Oxygen is a major component element of human and animal tissues and it is closely related with the metabolism of energy and mass. On the basis of low natural abundance of \(^{18}\text{O}\), Hou and Jiang\(^{(53)}\) studied the metabolism of oxygen in mouse body by tracer with enriched isotope of \(^{18}\text{O}\) and CNAA by measuring \(^{19}\text{O}\) (26.9 s) produced by \(^{18}\text{O}(n, \gamma)\(^{19}\text{O}\) reaction. Under time parameters of \(t_i = t_c = 20 \text{ s}, t_d = t_w = 3 \text{ s}\) and six cycles, 0.01% of variation of the concentration of oxygen in animal blood was observed. Fast neutron reaction \(^{19}\text{F}(n, p)\(^{19}\text{O}\) may interfere with the determination of \(^{18}\text{O}\); however, the low concentration of F in tissues (except bone and tooth) and low flux of fast neutron in the reactor make this interference not a serious problem.

4.2 Determination of Pb, F, Sc, and Ag in Environmental Samples

Lead is well known as a toxic element and its distribution as a pollutant is widespread. It is, therefore, of interest to determine its concentration in a variety of environmental materials. Lead cannot be determined by thermal NAA unless a very short-lived radionuclide \(^{207m}\text{Pb}\) was used.\(^{(54)}\) However, the half-life of \(^{207m}\text{Pb}\) of only 0.8 s makes it difficult to be measured using conventional NAA method. By using a fast transfer pneumatic system, Egan and Spyrou\(^{(22)}\) determined lead in some environmental samples. Under the conditions, \(t_i = t_c = 2 \text{ s}, t_d = t_w = 1 \text{ s}\), and 50 cycles, the sensitivity in an interference-free matrix
was found to be 5 µg, and a detection limit of 30 µg g⁻¹ was reported for biological matrix.

Owing to a high-resonance integral cross section of reaction $^{19}$F(\(n, \gamma\))$^{20}$F, Parry et al.\(^{(55)}\) determined fluorine in moss and soil sample with an improved detection limit by using epithermal neutron and cyclic activation.

Silver and scandium are usually determined by using their long-lived nuclides, $^{110}$mAg and $^{46}$Sc. However, the use of CNAA not only reduces the analytical time but also improves the detection limit of these two elements by using their short-lived nuclides, $^{110}$Ag and $^{46}$mSc. Chatt et al.\(^{(9, 20)}\) and Spyrou et al.\(^{(23)}\) have used CNAA to analyze some environmental samples for Sc and Ag as well as other elements, such as Dy, Hf, Se, Al, V, etc.

In addition, fast neutron CAA was also used for the determination of Pb and F in environmental samples by using reactions $^{208}$Pb(\(n, 2n\))$^{207}$Pb and $^{19}$F(\(n, p\))$^{19}$O; a comparable detection was reported for the determination of F by epithermal neutron CAA and fast neutron CAA.\(^{(55)}\) In addition to Pb and F, fast neutron CAA has also been used for many other elements such as As, Ce, Nd, and Hf.\(^{(59)}\)

### 4.3 Determination of O, Sc, Si, Al, Ag, Au, Rh, Pb, and U in Geological and Industrial Materials

CAA was proposed early by Caldwell et al.\(^{(3)}\) for the elemental analysis of lunar and planetary samples. Using this technique,\(^{(4, 5)}\) they successfully detected O, Si, Mg, and Al by fast neutron reactions, $^{16}$O(\(n, p\))$^{16}$N, $^{28}$Si(\(n, p\))$^{28}$Al, $^{24}$Mg(\(n, p\))$^{24}$mNa, and $^{27}$Al(\(n, \alpha\))$^{24}$mNa. Joshi and Agrawal\(^{(16)}\) determined Pb and Na in soil samples by using fast neutron reactions $^{208}$Pb(\(n, 2n\))$^{207}$mPb and $^{23}$Na(\(n, \alpha\))$^{20}$F under the condition of $t_i = t_c = 2.5$ s, $t_d = t_w = 0.4$ s and 14 cycles. Their results indicated that besides Pb and Na, other eight elements, such as O, Si, Mg, As, Ce, Hf, Nd, and In, could also be determined by this method. Chatt et al.\(^{(9)}\) determined Hf in Zirconium wire and Pb in brass by thermal neutron CAA, the detection limits reported are 0.93 µg g⁻¹ and 3.6%, respectively. Parry\(^{(35, 36)}\) analyzed some geological materials for Rh.

Ag by thermal neutron CAA and Au by fast neutron CAA; she also analyzed F in industrial samples by used fast neutron CAA.\(^{55}\) Owrang et al.\(^{56}\) reported a fast neutron CAA method for the in situ determination of oxygen in oil by using a neutron generator, a few milligrams of oxygen in oil sample has been determined, using this technique, the concentration of oxygen in metal oxides could also be measured.

Uranium is usually determined by measuring \(^{239}\)Np produced by \(^{238}\)U\((n, \gamma)\)^\(^{239}\)U\((\beta^-)\)^\(^{239}\)Np reaction. However, by measuring delay neutron after thermal neutron irradiation and cyclic activation, the detection limit can be significantly improved. In addition to geological sample, it can also analyze super-pure material, such as single-crystal silicon for uranium in nanogram per gram level. Song\(^{57}\) used this technique to analyze a variety of geological and industrial samples for uranium; a detection limit of 0.1 ng g\(^{-1}\) was reported.

5 CONCLUSION AND PERSPECTIVE

Since it was first proposed in the beginning of 1960s and rapidly developed in 1970s and 1980s, CAA has become a useful and mature technique for elemental analysis. Although some new CAA facilities were installed, in recent years, only some limited improvement on methodology was made. However, with the increase in CAA facilities, this technique is being applied in more wide fields, and with the increasing interest in using short-lived nuclides for activation analysis, CAA is attracting more attention. However, CAA, as one of the activation analytical techniques, can only be a supplement and not instead of the conventional activation analysis.

Comparing with conventional activation analytical techniques, CAA offers several advantages: (i) significant improvement of detection limit, analytical precision and accuracy for elements determined by using short-lived nuclides; (ii) short experimental time, hence reduced analytical expense and increased analytical capacity; (iii) capability of determining the degree of homogeneity of a sample by analyzing several portions of it for single cycles (cumulative activation); (iv) simultaneous determination of short- and medium-lived nuclides; and (v) estimating or confirmation of half-life of short-lived nuclides. However, CAA also has some disadvantages, e.g. (i) limited number of elements analyzed, i.e. only \(<50\%\) of elements analyzed by conventional NAA can be determined by CNAANAA; (ii) some special equipment or changes of normal equipment used in conventional activation analysis are needed; (iii) dead time and pileup correction must be made; (iv) interference from impurity elements in shuttle rabbit material cannot be avoided and a special compressed gas (such as \(N_2\), not air) should be used to transfer sample for reduced interference from \(^{41}\)Ar and other nuclides in activated air.

In comparing with nonnuclear analytical techniques, such as ICP–MS, owing to rapidity, nondestructive analysis, and in situ analysis, CAA as one of the activation analysis techniques is more competitive. However, with the improvement of ICP–MS technique (especially nondestructive analysis by laser ablation inductively coupled plasma mass spectrometry (LA–ICP–MS)) and its popularity, the application of CAA (including all activation analysis techniques) is becoming less.

ABBREVIATIONS AND ACRONYMS

\(\sigma\) Activation cross section
\(C\) Actual acquired net counts in photopeak of interest
\(f\) Correction factor for dead time in one cycle
\(F_n\) Correction factor for dead time of \(n\) cycles
\(F_p\) Correction factor for pileup
\(t_c\) Counting time
\(S/m\) Counts per unit mass element of interest
\(T\) Cycle period \((T = t_1 + t_d + t_c + t_w)\)
CAA Cyclic activation analysis
CNAANAA Cyclic neutron activation analysis
\(\lambda\) Decay constant \(\left(\lambda = \ln 2/\tau_{1/2}\right)\)
\(t_d\) Delay time (the time interval between the end of irradiation and the start of counting)
\(D_1\) Detector response (or the number of counts)
\(D_n\) Detector response in \(n\)th cycle
\(\varepsilon\) Efficiency of the detector
FNAANAA Fast neutron activation analysis
DT(t) Fractional analyzer dead time at time \(t\)
IAICP–MS Inductively coupled plasma mass spectrometry
\(I\) Intensity of the radiation of interest
LA–ICP–MS Laser ablation inductively coupled plasma mass spectrometry
NAA Neutron activation analysis
\(n\) Number of cycles
\(N\) Number of target nuclei
\(N^*\) Number of radioactive nuclei
PCAA Pseudocyclic activation analysis
\(L_d\) Qualitative detection limit
\[ \Phi \] Radiation (neutron) flux intensity
\[ \delta \] Relative standard deviation
\[ I_0 \] Resonance integral cross section
\[ \sigma_0 \] Thermal neutron activation cross section
\[ P \] The actual photopeak count rates including pileup
\[ P_0 \] The true photopeak count rates without coincidence losses
\[ T_c \] The live time of the measurement
\[ bD_c \] The cumulative detector response for the nuclide making the major background contribution to the signal from the nuclide of interest
\[ t_i \] Time of irradiation
\[ D_c(nD_c) \] Total cumulative detector response in all \( n \) cycles
\[ T_I \] Total experiment time
\[ A_0 \] True initial photopeak count rate
\[ t_w \] Waiting time (the time interval between the end of counting and the start of irradiation)

Further Reading 24

In 1976, a Canadian group described in detail for the first time a new ion beam analytical method based on the elastic recoil of target nuclei collided with high-energy heavy incident ions. In this case, 25–40-MeV 35Cl impinged on a multilayer C or Cu (backing)/LiF or LiOH/Cu (30–150 nm)/LiF or LiOH and H, Li, O, and F recoiled atoms were detected. These exemplified the main characteristics of elastic recoil detection analysis (ERDA): its sensitivity to depth distribution and its ability to detect light elements in heavy substrates. In 1979, the use of megar electronvolt energy 4He beams permitted the use of ERDA to be extended to depth profiling of hydrogen isotopes in the near-surface region of solids.

ERDA has rapidly been revealed to be an excellent alternative to resonant nuclear reaction spectrometry (see Nuclear Reaction Analysis) for hydrogen determination in solids. Despite its less advantageous performance with respect to its lower depth resolution, lower analyzable depth, comparable sensitivity, and more restricting irradiation and detection geometry, some ERDA features have made its development in ion beam analysis (IBA) laboratories worldwide easier; these are simultaneous access to 1H and 2H depth distributions, access to single-ended Van de Graaff accelerators compared with tandem accelerators or cyclotrons, and the ability to be combined with Rutherford backscattering spectrometry (RBS) (see Rutherford Backscattering Spectroscopy).

The development of detection devices and the analytical capabilities offered by high-energy heavy-ion-induced ERDA in material sciences for profiling light, medium, and high mass number elements give this method a wide area in which to progress. The main advantage of heavy-ion ERDA and quite unique feature among analysis techniques is the fact that all sample elements can be depth profiled in one measurement by single detector telescope. By means of Monte Carlo (MC) simulations, the interpretation and reliability of the results have increased greatly over the last few years.
1 INTRODUCTION

In 1976, L’Ecuyer et al.,(1) from the INRS-Energie Varennes (Québec), presented a paper that described in detail for the first time a new ion beam analytical method based on the elastic recoil of target nuclei collided with high-energy heavy incident ions, in this case, 25–40-MeV $^{35}$Cl impinging on a multilayer C or Cu (backing)/LiF or LiOH/Cu (30–150 nm)/LiF or LiOH. The work exhibited two of the main characteristics that established the technique of ERDA: sensitivity to depth distribution and the ability to detect light elements in heavy substrates.

The need to use high-energy heavy ions was a limitation to the development of this new analytical tool. In 1979, Doyle and Peercy published the first real example of the use of ERDA to determine hydrogen isotope depth profiles in the near-surface region of solids.(2)

At the same time, resonant nuclear reactions induced by energetic heavy ions were strongly promoted for the quantitative measurement of $^1$H, $^7$Li, $^{11}$B, $^{15}$N, and $^{19}$F. Ion beams between 3 and 20 MeV were successfully shown to be very efficient for hydrogen depth profiling.(3–7)

ERDA has been revealed to be an excellent alternative to resonant nuclear reaction spectrometry for hydrogen determination in solids. Despite its less advantageous performance with respect to lower analyzable depth, comparable sensitivity, and more restricting irradiation terms of irradiation and detection geometry, some ERDA features have made its use and development in IBA laboratories worldwide fast; these are simultaneous detection of not only $^1$H and $^2$H but also other elements, rapid development of detectors, and the great availability of small single-ended and tandem accelerators. As a result of detector development, especially in the case of TOF- and gas-ionization detectors, energies even below 10 MeV can now be used for high-resolution depth profiling.

In October 1996, Tirira, Serruys, and Trocellier, a group of French authors from Saclay published the first ion beam monograph entirely dedicated to ERDA.(8) This book has been used as the basis for the technical part of the present article and also as a bibliographical source.

In the following, we establish the theoretical basis of elastic recoil phenomenon, describe the experimental configurations generally adopted for elastic recoil spectrometry, and illustrate the analytical capabilities of ERDA for quantitative measurements in solids. Section 2 is devoted to general considerations of elastic collisions induced by megaelectronvolt $^4$He and heavier incident ions in a hydrogenated material. Section 3 presents the practical characteristics of elastic recoil spectrometry in terms of irradiation and detection geometry, analytical performance, and data processing. Section 4 gives details of the main methodological variations from conventional ERDA using a single surface barrier detector and more recent experimental improvements. Section 5 is devoted to the use of high-energy $^4$He ions and heavy ions for carrying out light-element profiling in solids. Section 6 contains some application examples of ERDA in a wide variety of fields from polymer science to semiconductor or thin-film technology.(9–11)

The concluding section of this article attempts to focus on the relevance of ERDA in comparison with resonant nuclear reaction spectrometry and secondary ion mass spectrometry (SIMS) (see Secondary Ion Mass Spectrometry as Related to Surface Analysis) for hydrogen determination in the near-surface region of solids. It also indicates the major trends in ERDA development since 1997.

2 SCATTERING PROCESS AND CONVERSION OF ENERGY SPECTRUM TO DEPTH PROFILE IN ELASTIC RECOIL DETECTION ANALYSIS

2.1 Kinematics

When an incident ion (mass $m$) with kinetic energy $E_0$ (a momentum $P_0$) interacts with a target atom (mass $M$) at rest through a purely elastic collision, the application of the conservation principles for total energy and momentum allows us to write Equations (1) and (2) (Figure 1):

$$E_0 = E + E'$$

$$P_0 = p + p'$$

with $E$, $p$, $E'$, and $p'$ the respective kinetic energies and momenta of the scattered incident ion and the recoiled target atom. Introducing $\theta$ and $\phi$, the respective laboratory angles of scattering for $m$ and $M$ (Figure 1), we obtain Equations (3) and (4) given by

$$E' = K'E_0$$

where

$$K' = \frac{4mm\cos^2\phi}{(m+M)^2}$$

![Figure 1](image-url) \(\text{Schematic view of the elastic collision } \frac{m}{M}.\)
and the angular relationship, Equation (5):

$$\tan \theta = \frac{\sin(2\phi)}{(m/M) - \cos(2\theta)}$$  \hspace{1cm} (5)

If \( m > M \), as for example when \(^1\text{H}\) is the target atom and \(^4\text{He}^+\) is the incident ion, the incident ion cannot be scattered from its incident direction through an angle greater than \( \theta_{\text{max}} \). This value is directly derived from the above equations, Equation (6):

$$\sin \theta_{\text{max}} = \frac{M}{m}$$  \hspace{1cm} (6)

For a \(^4\text{He}/^1\text{H}\) elastic collision, \( \sin \theta_{\text{max}} \approx 0.26 \) and \( \theta_{\text{max}} = 14.47^\circ \). For a usual recoil angle \( \phi \approx 30^\circ \), \( K' = 0.48 \), thus 2-MeV \(^4\text{He}^+\) gives protons recoiling from the target surface an energy of 960 keV.

The kinematics of the elastic collision is described in detail in two IBA handbooks by Chu\(^{42}\) and Tirira.\(^{8}\)

### 2.2 Cross Section

#### 2.2.1 Rutherford Scattering

The classical Rutherford formalism developed for a purely coulombian scattering leads to the well-known basic formula, Equation (7):

$$\left( \frac{d\sigma}{d\Omega} \right)_{\text{cm}} = \left[ \frac{zZe^2}{4E_0^{\text{cm}}\sin^2(\xi/2)} \right]^2$$  \hspace{1cm} (7)

where \( (d\sigma/d\Omega)_{\text{cm}} \) is the differential scattering cross section expressed in the center of mass system, \( z \) and \( Z \) are the respective atomic numbers of the incident ion and the target atom, \( e \) the elementary charge, \( E_0^{\text{cm}} \) the kinetic energy of the incident ion in the center of mass, and \( \xi \) the scattering angle in the center of mass.

In the laboratory system, Equation (7) becomes Equation (8):

$$\delta = \left( \frac{d\sigma}{d\Omega} \right)^L = \left( \frac{zZe^2}{4E_0} \right)^2 \frac{m + 1}{M} \frac{1}{\cos^3 \phi}$$  \hspace{1cm} (8)

It is obvious that

- \( \delta \) exhibits a minimum value for \( \phi \approx 0^\circ \);
- \( \delta \) tends to infinity when \( \phi \) tends to \( \pi/2 \); in this case, the projectile/target interaction cannot be described by the Rutherford model;
- \( \delta \) rapidly decreases as \( E_0 \) increases; and
- when \( M \gg m \), \( \delta \) is independent of the mass ratio.

In ERDA, Rutherford behavior is mainly observed for heavy-ion beams colliding with light target atoms (see Section 5) and for a \(^4\text{He}\) ion beam below 1 MeV.

#### 2.2.2 Non-Rutherford Cross Section

The Rutherford formula cannot be applied for elastic scattering/recoil spectrometry when the interaction potential between the incident ion and the target atom deviates from a pure coulomb potential. This can happen in two different cases. First, if the energy is high enough and secondly, in the low-energy case, if the two nuclei are screened by inner-shell electrons. The high energy at which elastic scattering/recoil cross sections begin to deviate from classic Rutherford behavior is called the threshold energy. It corresponds to the limit above which nuclear forces affect the interaction potential. Several authors have reviewed theoretical models combining a pure coulomb potential with a weak-perturbing nuclear contribution, as for example a Yukawa-like potential.\(^{13}\) Experimental measurements of the threshold energy have been made for several projectile–target nucleus couples\(^{14}\) and analytical formulations have been extracted.\(^{15}\)

Using \( R_0 \), the distance of closest approach as a free parameter, the threshold energy is expressed by Equations (9) and (10):

$$E_{\text{th}} = \left( \frac{ze^2}{2R_0} \right) \left( 1 + \frac{m}{M} \right) \left( 1 + \frac{1}{\cos \phi} \right)$$  \hspace{1cm} (9)

where, for example,

$$R_0 = C_1 + C_2(m^{1/3} + M^{1/3})$$  \hspace{1cm} (10)

\( C_1 = 6.003 \times 10^{-1} \text{m} \), \( C_2 = 0.864 \times 10^{-15} \text{m} \), and \( 5.2 < (m^{1/3} + M^{1/3}) < 8.6 \) (after Rääsänen).\(^{15}\) \( C_1 \) and \( C_2 \) are constants and \( m \) and \( M \) are the mass numbers. Applying this formalism, the threshold energy is \( 57.37 \text{MeV} \) for the couple \(^{35}\text{Cl}/^{12}\text{C} \) and \( 469.60 \text{MeV} \) for the couple \(^{127}\text{I}/^{16}\text{O} \).

In the case of heavy incident ions, the smaller cross sections due to the screening effect in low-energy scattering needs to be taken into account in the analysis. According to the analytical formula derived by Andersen et al.\(^{16}\) the deviation from the pure Rutherford cross section is 21.7, 10.4, and 1.5% for \(^{65}\text{Cu} \) recoils detected at 40° and ejected by 10 MeV \(^{197}\text{Au} \), \(^{127}\text{I} \), and \(^{35}\text{Cl} \) incident ions, respectively.

#### 2.2.3 \(^4\text{He}/^1\text{H}\) Collision

Historically, the scattering of protons by \(^4\text{He}\) target nuclei was first investigated in the range 1–20 MeV for \( E_p \). A phase shift analysis derived from quantum mechanics was thus applied to evaluate the cross section.\(^{17,18}\)

The reverse collision can be treated by the same approach in the range 1–4 MeV for \(^4\text{He}\). The decomposition of wavefunctions in partial waves can be restricted
to $S_{1/2}$, $P_{1/2}$, and $P_{3/2}$ contributions to describe the scattering of $^4\text{He}$ by $^3\text{H}$. This method consists in determining nuclear phase shifts by using physical models such as the optical model or the $R$-matrix theory.\(^{(19-23)}\) Tirira and Bodart have used experimental data below 4 MeV to extend previous phase shift studies.\(^{(24)}\)

The best set of theoretical parameters (scattering length and effective range), derived by Tirira and Bodart\(^{(25)}\) is presented in Table 1.

For $^4\text{He}$ energy values below 3 MeV and $\phi$ values below 30°, i.e. the most frequently used experimental conditions, several points with respect to the functional dependence of the non-Rutherford cross section $\delta_{\text{nr}} = (d\sigma/d\Omega)^L$ should be noted:

- $\delta_{\text{nr}}$ exhibits a minimum value for an energy $E_{\text{min}}$ in the range 2.4–3 MeV for a recoil angle less than 30° ($E_{\text{min}} = 2.41$ MeV at 0°). As the angle increases from 0°, the cross-section minimum moves toward larger energy values.
- $\delta_{\text{nr}}$ has its lowest value at $\phi = 0°$ for $E_{^4\text{He}} < E_{\text{min}}$.
- $\delta_{\text{nr}}$ has its highest value at 0° for $E_{^4\text{He}} > E_{\text{min}}$.
- $\delta_{\text{nr}}$ appears to reach the same constant value around $E_{^4\text{He}} = 3$ MeV for $0 < \phi < 40°$.
- $\delta_{\text{nr}}$ varies very slightly near 0° with respect to $E_{^4\text{He}}$.
- $\delta_{\text{nr}}$ varies slightly in the 0–30° range between 2 and 3 MeV.
- $\delta_{\text{nr}}$ shows a quasi-Rutherford behavior for $E_{^4\text{He}} < 1$ MeV.

Comparing previously published data sets and their own experimental results, Tirira and Bodart derived a simple analytical expression allowing the elastic recoil differential cross section in the laboratory to be calculated for any $E_{^4\text{He}} - \phi$ couple, Equation (11)\(^{(25)}\):

$$\ln \left( \frac{d\sigma}{d\Omega} \right)^L = A_1 E_{^4\text{He}} + A_2 + A_3 E_{^4\text{He}}^{-1} + A_4 E_{^4\text{He}}^{-2}$$

Table 2 contains different data sets for $A_i$ values, for $0 \leq \phi \leq 40°$ and $1 \leq E_{^4\text{He}} \leq 4$ MeV. Other binary collisions such as $^4\text{He}/^2\text{H}$, $^4\text{He}/^3\text{H}$, and $^3\text{He}/^4\text{H}$ have been treated in the same way.\(^{126-30}\) A detailed discussion on this subject and the corresponding analytical expressions are given by Tirira et al.\(^{(8)}\)

### 2.3 Energy–Depth Relationships

An incident ion with energy $E_0$ impinges on a target surface with an angle of incidence $\alpha$ with respect to the normal to the surface. Let us consider an elastic collision occurring at depth $x$ beneath the target surface, the scattering direction makes an angle $\theta$ with the incident direction and the recoil angle is $\phi$. The path of the incoming ion before collision is simply expressed by Equation (12):

$$L_{\text{in}} = \frac{x}{\cos \alpha}$$

Its outgoing path is given by Equation (13):

$$L_{\text{out}} = \frac{x}{\cos \alpha}$$

where the outgoing angle has been chosen to be equal to the incoming one. The path of the recoiled target atom is then given by Equation (14):

$$L_t = \frac{x}{\cos \beta}$$

where $\beta = \pi - \phi - \alpha$.

The energy of the incident ion just before the collision is given by Equation (15):

$$E_0(x) = E_0 - \int_0^{x/\cos \alpha} S(E) \, dl$$

where $dl$ is the differential path. The energy of the scattered incident ion leaving the target is given by Equation (16):

$$E_1(x) = KE_0(x) - \int_0^{x/\cos \alpha} S(E) \, dl$$

and the energy of the recoiled target atom is given by Equation (17):

$$E_2(x) = K'E_0(x) - \int_0^{x/\cos \beta} S_t(E) \, dl$$
where $S(E)$ and $S_r(E)$ are the stopping powers for the incident ion and the recoiled target atom, respectively, in the target material considered.

2.4 Recoil Yield

For a thin target, the number of recoiled target atoms emitted in the depth range $x - x + dx$ through an angle $\phi$ in the solid angle $\Delta \Omega$ is given by Equation (18):

$$
\frac{dN(x)}{dx} = N_0 Q \frac{d\sigma(E, \phi)}{d\Omega} \frac{\Delta \Omega}{\Delta \Omega}
$$

(18)

where $N_0$ is the target atomic density and $Q$ the total number of incident ions. The total recoil yield is then obtained by integrating Equation (18) on the thickness $t$ of the target sample, considering the differential cross section as constant along $t$.

For a thick target, the analytical expression giving the recoil yield is slightly more complex because it has to take into account the variation of the differential cross sections with energy and all the energy spreading effects induced by particles traveling in matter.

2.5 Depth Resolution

Depth resolution $\delta R_x$ strongly depends on total energy resolution of the system $\delta E_T$. This factor includes

- the detector energy resolution $\delta E_d$;
- the fluctuations in projectile energy $\delta E_p$;
- the energy spreading due to angular deviations $\delta E_\theta$;
- the geometrical energy spreading $\delta E_g$;
- the energy straggling during incoming and outgoing paths $\delta E_s$;
- the multiple scattering contribution $\delta E_{ms}$;
- the contribution from Doppler effect $\delta E_D$;
- the energy spreading due to the absorber $\delta E_a$; and
- the energy spreading due to surface roughness $\delta E_{rou}$.

A detailed description of the methods used for evaluating each contribution has been given by Tirira et al. (8)

3 CONVENTIONAL ELASTIC RECOIL SPECTROMETRY

3.1 Glancing (Reflection) Geometry

Figure 2 summarizes the experimental configuration called glancing or reflection geometry.

Several points should be noted:

- The beam spot size is enhanced by a factor $(1/\cos \alpha)$ with respect to normal incidence owing to the oblique incidence $\alpha$.

3.2 Transmission Geometry

Figure 3 summarizes the experimental configuration called transmission geometry.

Transmission geometry was the first experimental configuration used for ERDA measurements. (11,31–33)

Several points should be noted:

- The presence of an absorber foil in front of the surface barrier detector is not necessary because the target itself slows down the scattered ions while they travel along their path until they are stopped.
- Practically, the surface barrier detector has to be placed as close as possible to the $0^\circ$ direction, but not directly in view of the incident beam direction to avoid severe irreversible damage in the case of target breaking.
- The analyzable depth is only limited by the range of recoiling protons; it can reach up to 6–7 $\mu$m for polymer or silica-based materials. (34,35)

Figure 4  Examples of ERDA spectra obtained with a 1.8 or a 3.5-MeV $^4$He ion millibeam. (a) Thin hydrogenated NiC/Ti multilayer coated on a silicon substrate in reflection geometry and (b) thick hydrogenated amorphous carbon layer in reflection geometry.

Table 3 permits comparison of the analytical performances offered by the two available geometries for hydrogen measurement.

Figure 4 gives two different examples of ERDA spectra obtained in glancing geometry for a hydrogenated NiC/Ti multilayer and a thick hydrogenated amorphous carbon layer in reflection geometry.

3.3 Data Processing

Conventional ERDA data are treated in the same way as RBS, using a reconstitution-comparison-iteration computer program. The first step in the process is to define the experimental configuration (incident energy, geometry, detector characteristics, and target description). Then a simulated spectrum is built using the collision kinematic equation, the energy-loss formalism, the elastic recoil cross-section table, and straggling and multiple scattering subroutines. Finally, the simulated spectrum is compared to the experimental data and adjusted in terms of elemental distributions, using a classical least-squares method until it matches correctly.

Several authors have proposed specific computer codes dedicated to ERDA interpretation. Our purpose, in this section, is not to describe in detail any specific approach. The references listed above constitute excellent starting points to get to know classical IBA tools. An IAEA intercomparison of some of the most used computer codes was published recently.

In the case of heavy-ion elastic recoil detection analysis (HI-ERDA), another approach known as slab analysis is often used instead of simulation and comparison. In the energy spectrum, a channel corresponds to a certain depth slice. The depth is calculated using scattering kinematics and either experimental or, more often, semiempirical stopping powers. The yield at different depths is then normalized using stopping powers and scattering cross sections for a given incident ion and sample atoms. If all the sample elements can be analyzed, the final depth profiles can be normalized to unity to obtain the atomic ratios. All the effects degrading depth resolution that are mentioned above are still visible in the depth profiles after slab analysis.

3.4 Standard Matrices and Ion-beam-induced Damage

IBA techniques are considered to be quantitative even without the use of reference samples provided that the differential cross section of the interaction observed is accurately known in the energy range investigated and also provided the experimental geometry (target and detector) is fully described.

However, the quantitative determination of any elemental depth distribution in a complex target material generally requires the use of a reference sample. This standard (or model sample) is investigated either to simplify the calculation procedure or to assess the profile extraction method. Moreover, finding a good hydrogen reference sample remains a particular problem owing to its high mobility in solids even under standard temperature conditions. The use of reference samples is highly recommended for accurate results in the case of HI-ERDA also; even in the case of thin films when all the elements present can be detected and concentrations normalized to unity.

Polymers would represent the most practical type of hydrogen reference samples because of their large H
content, their variety of formulation, their thickness range (from 3 µm up to several hundred micrometers) and their well-known core composition homogeneity. Nevertheless, there are two severe limitations:

- the thickness heterogeneity of thin films having thickness less than 20 µm and
- the sensitivity of polymer structure to ion beam bombardment.

Elemental losses are impossible to prevent and in practise polymers have to be replaced by hydrogen-implanted monocrystals (Si or Ge, for example). The versatility of implantation conditions (energy and fluence) is of major interest but conservation of the hydrogen profile for long periods of time is not guaranteed. The hydrogen mobility in silicon at 25°C is far from negligible. Metal hydrides such as TiH₂ or Ti₃D_y (with x = 1 and y ≈ 1.8) could be an alternative to implanted crystals, but control of the stoichiometry is rather difficult. Hydrogenated amorphous carbon or silicon-carbide layers appear now to be a better compromise than hydride layers.¹¹

The choice of a multielemental reference sample requires a complete description of the investigated sample. Routine methods such as electron microprobe analysis (see Scanning Electron Microscopy in Analysis of Surfaces) must be very efficient to ensure the lateral composition homogeneity of the target material. The most important criterion is to choose a reference material with a similar composition in order to be able to neglect corrections for stopping power. Ceramics, glasses, or thin layers are the most useful materials for IBA standards provided that their sensitivity to ion bombardment has been checked before use.

Several effects can be inferred by an incident ion beam impinging on a radiation-sensitive material: electron excitation, ionization, atomic displacement, bond breaking, formation of charge defect centers, temperature increase, growth of an electrical gradient, and surface sputtering. The main consequences of these phenomena is the modification of the target composition and particularly the loss of certain elements of interest such as hydrogen, alkali metals, or halogen elements. An extensive review of beam damage is presented by Tirira et al. A comprehensive bibliography is given and concrete examples discussed.

### 3.5 Microbeam-induced Elastic Recoil Detection Analysis

Microbeam-induced elastic recoil detection analysis (µERDA) is the only routinely available technique for hydrogen determination using a nuclear microprobe. Experiments in transmission geometry are, in general, easier to carry out than experiments in reflection geometry.

Transmission geometry is used in polymer science applications or in geological applications and reflection geometry is chosen for thin-layer characterization.

Figure 5 gives an example of an ERDA spectrum obtained in transmission geometry on a thin polyimide film (25 µm) preirradiated with 50-MeV ³²S ions and measured with a 3.05-MeV ⁴He⁺ microbeam (5 × 5 µm², 200 pA). The heavy-ion irradiation induces the formation of hydrogen bubbles in the core of the modified polymer structure. Two of these hydrogen-rich zones are found in the spectrum between 3 and 5 µm from the surface.

### 4 VARIANT RECOIL METHODS

The energy discrimination between a scattered incident ion and a recoiled target atom is one of the major problems to be solved in ERDA. It can be based on the difference of energy loss in a given thickness of a well-known material. When m > M (⁴He/¹H collision), the scattered ⁴He loses a higher fraction of its energy than the recoil ¹H reaching the detector. The use of an absorber foil (polymer or Al) in front of the detector allows discrimination by stopping the scattered events. This simple technique is currently the most adopted one for ERDA measurement (see Section 3) in transmission geometry, in which the target itself plays the role of the absorber foil. When m < M, this system is completely inefficient.

#### 4.1 ΔE–E Telescope

The second way to solve the scattered/recoil event ambiguity is to replace the absorber foil by a thin detector (10–20 µm). The device constituted by a couple of detectors is called a solid-state ΔE–E telescope.
Scattered ions are stopped in the $\Delta E$ detector and recoil events are detected in the $E$ detector ($\geq 100 \mu m$). Figure 6 is a scheme of such a detection device.

The solid $\Delta E$ detector can be replaced by a gas-ionization chamber. Telescopes have been used for ERDA measurements with $^4$He beams as well as with heavy-ion beams.

The mass and charge separation ability of a telescope are simply described by Equations (19) and (20):

$$\frac{\Delta M}{M} = \left[ \left( \frac{\Delta E_R}{E_R} \right)^2 + \left( \frac{\Delta dE}{dE} \right)^2 + \left( \frac{\Delta dx}{dx} \right)^2 \right]^{1/2}$$  \hspace{1cm} (19)

$$\frac{\Delta Z}{Z} = \frac{1}{2} \left[ \left( \frac{\Delta E_R}{E_R} \right)^2 + \left( \frac{\Delta dE}{dE} \right)^2 + \left( \frac{\Delta dx}{dx} \right)^2 \right]^{1/2}$$  \hspace{1cm} (20)

where $dE$ is the energy loss in the thin detector and $dx$ is the thickness of the thin detector.

The presence of an absorber foil in front of the detector in conventional ERDA induces a high straggling contribution in the total depth resolution. The use of a $\Delta E-E$ telescope eliminates this straggling contribution because the recoil energy can be simply deduced by summing the energy loss in the thin detector $\Delta E$ and the residual energy $E_R$. Only the straggling contribution from the detector dead layers cannot be suppressed. For example, a depth resolution better than 25 nm has been obtained for oxygen determination in native oxide layers using a 43-MeV $^{65}$Cu beam. Siegel et al. have obtained a depth resolution better than 20 nm on stainless steel with 130-MeV $^{127}$I ions. A value of 10 nm has been obtained by Assman.

Figure 7 illustrates the increased selectivity offered by the use of a solid-state telescope for simultaneous detection of $^1$H, $^2$H, and $^3$H with 4-MeV $^4$He$^+$ in a titanium hydride layer.

4.2 Time-of-flight Elastic Recoil Detection Analysis

The determination of mass separation between scattered and recoil ions by measuring the difference in their time of flight (TOF) for a given path length was first introduced in the mid-1980s. The principle of TOF spectrometry is based on the measurement of particle flight time between a start gate and a stop gate giving two distinct signals. Simultaneously, the total energy of the particles is measured by means of a solid-state or gas-ionization detector. Figure 8 schematically describes a TOF spectrometer.

The flight time $t_f = t_2 - t_1$ of a particle with mass $M$ and energy $E_R$ traveling along a path of length $L$ is given by Equation (21):

$$t_f = t_2 - t_1 = L \left( \frac{M}{2E_R} \right)^{1/2}$$  \hspace{1cm} (21)

If the TOF spectrometer is set up with an entrance window of thickness $x$, Equation (20) becomes Equation (22):

$$t_f = L \left( \frac{M}{2E_R - S(E)x} \right)^{1/2}$$  \hspace{1cm} (22)

where $S(E)$ is the stopping power of the window material for recoil ion $M$ at energy $E_R$.

The time detector is generally an electrostatic mirror protected by a thin carbon foil ($0.5-20 \mu g \cdot cm^{-2}$) so that the energy recorded by the surface barrier detector, which is also often used as the stop-signal detector, is given by Equation (23):

$$E = E_R - S(E) x$$  \hspace{1cm} (23)
where \( x \) is the thickness of one or, in the case of two timing gates, two carbon foils. The carbon foil of the first electrostatic mirror serves as the entrance window for the TOF spectrometer. Typical flight time values are in the range 30–100 ns for a flight path of about 50 cm. Normally, the energy spectra used in the analysis is converted from timing signal. The two main reasons for this are (i) the normally better resolution for other elements than for H and He and (ii) the linear calibration for all the elements, which is not the case for a solid-state detector. A well-known limitation of the TOF-E technique is the poor detection efficiency (typically 10–60%) of timing gates for H, which is strongly stopping force and therefore, energy dependent. An elegant way to get around this limitation is to use the fact that for elements heavier than B, the detection efficiency is very close to 100%, and if the timing window is long enough, almost all noncoincident events seen only by the E detector are hydrogen. By summing up coincident events from the H curve and noncoincident events, 100% detection efficiency is obtained for H. This technique is described in detail in two round-robin characterizations where H was also studied.\(^{59,60}\)

Figure 9 gives an example of the application of a TOF spectrometer for the ERDA characterization of a glass ceramic bombarded by an 84-MeV \( ^{127} \text{I} \) beam.\(^{8}\) It can be seen that the mass resolution is less than 1 for low masses, and that \( ^{10} \text{B} \) and \( ^{11} \text{B} \) isotopes are clearly distinguishable. Nevertheless, mass resolution decreases with increasing mass so that \( ^{27} \text{Al} \) and \( ^{28} \text{Si} \) cannot be separated. This is mostly due to poor energy resolution of the solid-state detector. The mass resolution can be drastically improved by introducing a gas-ionization detector equipped with a thin SiN entrance window.\(^{61}\) However, Al and Si can be readily separated with a \( \Delta E - E \) gas detector as shown by Siegele et al.\(^{54}\)

A characteristic feature for TOF-ERDA is the fact that depth resolution at the surface improves when the energy of incident ion is lowered. This is due to the fact that the elemental energy spectra used in the analysis are converted from TOF spectra. Even with a simple TOF-E telescope, all elements below Ne can be separated from each other with projectile (Cl, Br, and I) energies below 20 MeV.

4.3 Coincidence Spectrometry

In the first ERDA experiments, from Cohen in 1972\(^{31}\) to L’Ecuyer in 1976,\(^{11}\) transmission geometry together with coincident detection of scattered and recoil particles were applied to achieve mass selectivity, to reduce the background, and to improve the sensitivity.

By detecting both particles, four parameters can easily be obtained: \( E_\text{S}, E_\text{R}, \theta, \) and \( \phi \). Thus the mass of the recoil nucleus \( M \) and the interaction depth \( x \) can be deduced according to Figure 10. One variation of this technique, proton-proton scattering utilized by Reichart et al., allows sensitive 3D profiling of hydrogen down to ppm-levels.\(^{62}\)

Two families of ERDA coincidence methods can be distinguished: those carefully adjusting \( \theta \) and \( \phi \) to achieve mass selectivity and to reduce the background, and those carefully measuring \( E_\text{S} \) and \( E_\text{R} \) to eliminate \( \theta \) and \( \phi \).

Depth information is the ultimate goal of the first family of methods; this can be deduced from energy measurement. Large solid detectors are generally used in the second family of methods, and as a result, depth resolution is sacrificed. Figures 11 and 12 give one example of the application of each method.

Partial separation of \( ^{63} \text{Cu} \) and \( ^{65} \text{Cu} \) has been obtained by Klein et al.\(^{63}\) using a pair of position-sensitive detectors at the GSI heavy-ion microprobe (Darmstadt,
Figure 11 Coincident elastic recoil detection spectra of two thin Cu films separated by LiF measured with $^{58}$Ni ions. The final target is different from the initial one because the outer LiF layers have been partially decomposed during the irradiation. (Reproduced with the kind permission of Elsevier Science and Plenum Press.)

Germany) on a sandwich target (LiF/Cu/LiF/Cu/LiF) with 1.4-MeV amu$^{-1}$ $^{58}$Ni ions. The dominant peak in Figure 12(a) corresponds to recoiled carbon atoms; recoiled oxygen is seen in the spectrum at higher He energies. Figure 12(b) is similar to Figure 12(a), but rotated by 180°, the surface line corresponds to the scattering process at the rear surface of the target.

4.4 Electromagnetic Cross Filters ($E \times B$)

The Canadian group from Varennes was the first to propose the use of an electromagnetic cross filter as an achromatic mass and charge selector and not only as a Wien filter. A typical $E \times B$ (electric and magnetic crossed fields) device for ERDA measurement is shown in Figure 13.

When a particle passes through the $E \times B$ filter, Equations (24) and (25) describe its exact movement:

$$m \frac{dv_y}{dt} = q(E - v_x B)$$

$$m \frac{dv_x}{dt} = q v_y B$$

Assuming $v_x = v_0$ and $v_y = 0$, they reduce to Equation (26):

$$m \frac{dv_y}{dt} = q(E - v_0 B)$$

At the exit of the filter, the particle is deviated by an angle $\alpha$ given by Equation (27):

$$\sin \alpha \approx \alpha = \frac{q L(E - v_0 B)}{m v_0^2}$$

where $L$ is the total length of the $E \times B$ filter.

The filter should deflect particles of all energies by the same angle; this condition is satisfied when Equation (28) applies:

$$\frac{d\alpha}{dE} = 0 \quad \text{or} \quad E = \frac{B v_0}{2}$$
Typical values for $L$, $B$, and $E$ are, respectively, 70–80 mm, 1 kG, and 1.5–2 kV cm$^{-1}$.

Electromagnetic cross filters have been evolving since 1995 and more sophisticated devices have appeared such as the $B - E \times B - B$ filter proposed by Serruys, which has been described previously.$^{(8)}$

The Canadian group from INRS Varennes and A. Chevarier’s group in France (Lyon University) have collaborated together on the use of the $E \times B$ filter to characterize amorphous hydrogenated layers. They have shown that hydrogen desorption induced by 2.5-MeV $^4$He$^+$ with or without previous deuterium implantation was smaller for a-SiC:H than for a-C:H layers.$^{(11)}$ Figure 14 compares the hydrogen distributions in a-SiC:H and a-C:H layers after a deuterium implantation at a level between 2.2 and $3.5 \times 10^{16}$ D cm$^{-2}$.

5 HIGH-ENERGY AND HEAVY-ION ELASTIC RECOIL SPECTROMETRY

As discussed in Section 2, low-energy $^4$He (2–4 MeV)-induced ERDA is adapted to profile target nuclei lighter than the projectile: generally $^1$H and $^2$H. Using a specific coincidence detection device allows the researcher to extend the profiled mass range to target nuclei heavier than the projectile (see Section 3). There are two other means to improve the range of analyzable elements and the total explored depth. The first consists in increasing the energy of the incident $^4$He beam to improve the energy separation between the contributions of the different target components and also to take advantage of the increase in the non-Rutherford cross section for light elements.$^{(67,68)}$ The second consists in increasing both the mass and the energy of the incident ion beam; this technique is called high-energy HI-ERDA.$^{(48,69–71)}$ The selectivity is thus largely improved; this was the configuration adopted by L’Ecuyer et al. in 1976 to investigate multilayered structures.$^{(1)}$

5.1 High-energy $^4$He-induced Elastic Recoil

When $^4$He incident energy increases above 1 MeV, Rutherford scattering is no longer an applicable model. High-energy $^4$He scattering in light elements has a non-Rutherford behavior and cross-section resonances exist for several couples $^4$He/target nucleus, as shown in Figure 15 for carbon and oxygen.

Figure 16 shows the ERDA spectrum for $^{12}$C recoil of an Al/C sandwich target, obtained using a 30 MeV $\alpha$-particle beam in transmission geometry.

5.2 High-energy Heavy-ion-induced Elastic Recoil

Equation (4), describing the kinematics of the collision $m/M$, with $m \gg M$ becomes Equation (29):

$$E' = 4E_0 \cos^2 \phi \frac{M}{m}$$  \hspace{1cm} (29)

The interaction cross section follows Rutherford behavior as long as the incident energy is below the threshold energy defined by Equation (9).

The analytical expression of the differential recoil cross section given by Equation (8) becomes Equation (30):

$$\frac{d\sigma}{d\Omega} = \left( \frac{Ze^2}{2E_0} \right)^2 \left( \frac{m/M}{m} \right) \cos^3 \phi$$  \hspace{1cm} (30)

Several points should be noted:

• The differential cross section is nearly independent of the recoil mass because the $(Z/M)$ ratio ranges...
between 0.4 and 0.5 for all the elements except hydrogen.

- For hydrogen recoils \((Z/M) = 1\) and the differential cross section is increased by a factor of four relative to the other recoiled target atoms.

- The sensitivity of high-energy HI-ERDA increases strongly with increasing \(z\). Anyhow, if a sophisticated detection system like \(\Delta E - E\) or TOF-E is used in the analysis, the high-\(z\) projectile does not necessarily provide the lowest detection limit, but that can be obtained with lighter projectiles giving more energy and therefore better separation in the 2-D histogram for the recoils.

- The selectivity of high-energy HI-ERDA decreases with increasing \(Z\). For example, C, N, and O can be separated well in stainless steel using a 136-MeV \(^{127}\text{I}\) beam,\(^{75}\) but transition elements such as Cr, Fe, and Ni cannot be properly separated using 136-MeV \(^{127}\text{I}\) and the Bragg counter as shown in Figure 17. Nevertheless, Siegele et al. have shown that this separation is possible at 136 MeV, using a telescope with a gas chamber as the \(\Delta E\) detector.\(^{76,77}\)

- The differential cross section increases with increasing recoil angle \(\phi\) (factor 5 between 30 and 60°), but simultaneously the recoil energy is reduced. Generally, the detector system is located around 40°.

High-energy HI-ERDA requires specific detection devices such as those described in Section 4 (TOF...
ELASTIC RECOIL DETECTION ANALYSIS

Figure 17  Two-dimensional plot (maximum energy loss/recoil energy) obtained on stainless steel with 136-MeV $^{127}$I.\(^{(75)}\) (Reproduced with the kind permission of Elsevier Science and Plenum Press.)

spectrometer or telescope). Electrostatic or magnetic spectrometers and ionization chambers are also in use.\(^{(68)}\) Data processing is generally based on two or more parameter data acquisition and the elemental information is expressed in matrix form.

The analytical performance offered by high-energy HI-ERDA, particularly depth resolution, depends strongly on the total energy resolution of the detection system, on the nature and energy of incident ions and recoil particles, and on the depth where the collision has occurred. Dollinger et al. have reported a surface depth resolution of 8 nm for hydrogen determination in a thin carbon film bombarded by 120-MeV $^{197}$Au ions in transmission geometry using a large magnetic spectograph.\(^{(69)}\) For carbon/boron multilayers deposited on a thick silicon substrate, a surface depth resolution of less than 1 nm is achieved in reflection geometry using the same beam parameters.\(^{(69)}\) With low-energy ions and standard TOF-E telescope Brijs et al. demonstrated a depth resolution of 2 nm at the surface for H, N, and Si when characterizing very thin SiO$_2$/Si$_3$N$_4$/SiO$_2$ film stacks using glancing angles.\(^{(77)}\) Measurement using 6-MeV $^{35}$Cl incident ions and very glancing 3 + 35 = 38 angle in reflection geometry is presented in Figure 18.

Normal ERDA geometry with the detector around 40° also offers good possibilities for the use of forward scattered incident ions, in addition to recoils, in the analysis. One possibility is to use light incident ion and do forward scattering analysis. The benefit of this is the high cross section and good depth resolution because of the small energy spread due to multiple scattering and kinematics. An example of this is the study of 6-nm HfSiO and 25-nm NiSi films on silicon using 3–8-MeV $^{16}$O ions as projectiles.\(^{(78)}\) The use of scattered incident ions with recoiled target atoms in the analysis is demonstrated in Figure 19 where an atomic layer deposited Li–La–O film was measured using a 16-MeV $^{63}$Cu beam. The recoiled La atoms suffered greatly from multiple scattering and could not be used in the analysis without proper MC simulations, but as La is the only heavy element present, scattered $^{63}$Cu could be used instead. As two different scattering cross sections were used, the scattering angle had to be known very accurately.

Figure 18  A metalorganic chemical vapor deposited Si$_3$N$_4$ film with some H and O impurities measured with 6-MeV $^{35}$Cl beam using 3.2° incident and 35° recoiling angles. (a) A TOF-E histogram of the measurement showing all the sample elements and (b) the depth profiles converted from elemental TOF spectra using slab analysis approach. Density of 3.3 g cm$^{-3}$ was used in conversion of the depth scale to nanometers.
The main limitation on analytical performance in high-energy HI-ERDA (depth resolution, sensitivity, or analyzed depth) is attributed to the behavior of the target material under ion bombardment. In the case of films with a thickness of the order of nanometers, the sputtering phenomenon, which is directly proportional to the nuclear energy loss, has to be taken into account when analyzing the measurements. In the case of thicker films, especially of polymers, a much more visible effect is the loss of light elements throughout the film thickness. In the case of porous low-\( k\) materials, the losses were found to be directly proportional to the energy loss of incident ions in the films and therefore to minimize the losses, the heaviest possible ion had to be used in the analysis.\(^{(79)}\)

Figures 20 and 21 give two different examples of the use of high-energy HI-ERDA. The first example deals with the analysis of an 80-nm silicon oxynitride film coated on 30-nm \( \text{SiO}_2 \) deposited on Si with 30-MeV \( ^{28}\text{Si} \) ions.\(^{(80)}\) The second example is dedicated to the characterization of a 15-nm Al/Cu multilayer deposited on silicon by using a 200-MeV \( ^{197}\text{Au} \) ion beam.\(^{(81)}\)

Another general feature of HI-ERDA that has a great effect on the analysis reliability is multiple scattering, which, for more detailed analysis, can be divided to multiple and plural scattering. This multiple scattering causes angular spread, which can be described with analytical functions.\(^{(82-84,85)}\) Equally important in the analysis are events where the scattering occurs closer to the sample atom nucleus resulting in a large angle...
scattering. Although these events are scarce, they can play an important role in the analysis. These scatterings are referred as plural scattering. Due to the nature of these events, no analytical function has been used to simulate them and they require full MC simulations. Multiple and plural scattering effects are strongly enhanced if the studied sample contains heavy elements; to carry out a very detailed analysis, the MC-simulation program should be used. The most sophisticated one at the moment is MCERD by Kai Arstila,\cite{86} which can, due to several computational enhancements, do full simulations in roughly the same time as it takes to measure the sample. In Figure 22 an example of the use of MCERD in the analysis is shown for the same measurement as in Figure 18. The experimental energy spectra are well reproduced; the low-energy tails, and reliable depth profiles are also obtained. The conclusion of rising Si content deeper in the film drawn on the basis of slab analysis (Figure 18) can be proven to be wrong by MC-based analysis. In addition to MC simulations, also Molecular Dynamics simulations have a great potential in interpreting IBA results.\cite{87}

6 APPLICATION EXAMPLES OF ELASTIC RECOIL DETECTION ANALYSIS FOR PROFILING HYDROGEN AND OTHER ELEMENTS

Four main application fields can be essentially distinguished for ERDA measurement, using either a low-energy $^4$He beam, higher energy $^4$He, or heavier ions: polymer science, microelectronics, thin films, and interface reactions. Each of these fields is illustrated in this section.

6.1 Polymer Sciences

Polymers are the most hydrogenated media encountered among solids. Three complementary topics of interest have given rise to the development of ERDA-based studies: the investigation of polymer surface properties, the hydrogen distribution in polymer blends and the irradiation behavior of polymers.

Many application examples have been presented and discussed by Tirira et al.\cite{8} Only some of them are presented in this article.

For example, Chou et al. have studied the modifications induced by radio frequency or microwave treatment under a D$_2$O atmosphere of polyimide films. They showed that the polyimide surface exhibited a D uptake proportional to the time of treatment.\cite{88} Moreover, a correlation has appeared between the surface concentration of hydroxy groups and the development of surface morphology during plasma treatment.

Green et al. studied the segregation of deuterated copolymer (molecular weight $M$ in the range 87 000–520 000) at the interface of a homopolymer blend.
NUCLEAR METHODS

(polystyrene/poly(vinyl methyl ether) with a molecular weight between 100,000 and 200,000) using 2.8-MeV $^4$He ions. They have shown that the diffusion coefficient of deuterated polymer varies as $M^{-2}$.

Composto et al. measured the diffusion coefficient of polymer molecules (deuterated polystyrene and deuterated poly(xylenyl ether) chains) in a complex polymeric structure using D as a tracer. Diffusion coefficients have shown to be independent of the matrix molecular weight and to decrease as $M^{-2}$.

Several authors have applied ERDA to evaluate the degradation of polymer composition under charged-particle bombardment. Wang et al. have investigated the modification of the electrical conductivity of high-temperature and high-performance polyetheretherketone (PEEK) and polyethersulfone polymers by ion implantation (50 and 180 keV As and Xe ions). A two-component regime has been found in which dominance depends on the implantation fluence ($<10^{15}$ ions cm$^{-2}$ or $>10^{17}$ ions cm$^{-2}$). Another example of ERDA study of polymer degradation was given in Section 3. Figure 5 corresponds to the application of $\mu$ERDA for polymer characterization after high-energy heavy-ion bombardment. In this case, 50-MeV $^{32}$S ions were previously used to irradiate thin polyimide foils (25 $\mu$m). Bombardment-induced bond breaking leads to the formation of hydrogen-rich zones (micrometric bubbles or association of nanometric bubbles) trapped in the degraded polymer structure, as seen in Figure 5.

6.2 Semiconductor Materials

In this area, ERDA measurements are generally dedicated to profiling successive thin layers coated on a crystalline semiconductor substrate (Si, Ge, or GaAs) having different compositions and thicknesses.

The hydrogen profile is measured using a conventional approach with $^4$He ions as shown by Wang et al. or Barbour et al. Other light elements such as C, N, and O have been profiled using high-energy HI-ERDA.

Wang et al. have profiled hydrogen in semi-insulating polysilicon films. Figures 23 and 24 show the hydrogen recoil spectra obtained on films immersed in a gas flow reactant mixture ($N_2O/SiH_4$) in various ratios or annealed between 700 and 1000 °C for 30 min for a given gas reactant ratio. The film deposition rate decreases when the $N_2O/SiH_4$ ratio increases owing to the increase in oxygen concentration. The H content of the film decreases when the annealing temperature increases owing to the densification and restructuring of the film.

Barbour et al. have shown that for silicon nitride film deposition by electron cyclotron resonance, the hydrogen content of the film was minimized when the stoichiometry was closest to $Si_3N_4$.

Figure 23  Hydrogen recoil spectra for polysilicon samples immersed in a $N_2O/SiH_4$ flow with various $N_2O/SiH_4$ ratios. (Data reproduced from Wang et al., with the kind permission of Elsevier Science and Plenum Press.)
6.3 Thin Films

In the case of thin-film monolayered or multilayered structures, ion beam methods have been revealed to be powerful characterization tools, particularly considering the HI-ERDA\(^{94}\) and coupling of RBS with ERDA.\(^{95–97}\)

The development of materials based on hydrogenated amorphous carbon “diamond-like” or silicon-carbide layers, because of their promising tribological properties, strongly influenced the interest in ERDA in the early 1990s.\(^{98–101}\)

The relationship between the optical and electrical properties of hydrogenated amorphous silicon carbon films and their stoichiometry have been determined combining RBS and \(^4\)He-induced ERDA by Compagnini et al.\(^{95}\) A hydrogen concentration of 30 atom\% was shown to increase the optical energy gap by a factor of two and the electrical resistivity by several orders of magnitude.

Figure 25 gives three recoil spectra obtained on a:C–H or a:C–D layers. Hydrogen implantation in the a:C–D layer was shown to induce a large surface D release,\(^{99}\) extending to at least 80% of the analyzed depth (0–0.3 \(\mu\)m). Microelectronics is an important driving force in the development of this method. IBA has played an important role in the development of films replacing SiO\(_2\) as a gate oxide\(^{102}\) and the role of IBA in the film development has been very important. Another important thin-film application related to microelectronics has been Cu diffusion barriers like TiN\(^{103}\) and TaN.\(^{104,105}\) During the development process, deposited films normally contain substantial amounts of H, C, and O due to the precursors used – HI-ERDA can easily provide this information.

6.4 Interface Reactivity

This field of application corresponds to the experimental study of atomic transport mechanisms near a solid/solid or a solid/liquid interface, for example, oxide corrosion behavior,\(^{106,107}\) wear properties of treated metal, amorphous layers, or glass surfaces.\(^{108–113}\) Intensive use of ERDA has been reported by the Canadian group from Varennes\(^{114}\) and by the French group from the University of Lyon.\(^{111}\) These two groups have collaborated in studying some candidate materials for fusion reactor device coatings that act as facings for the plasma. Essentially, they studied hydrogen loss under irradiation and annealing conditions.

Figure 26 shows the erosion of the hydrogen depth profile in an a:C–H layer after \(^4\)He\(^+\) bombardment at
6.5 Other Application Examples

Other conventional ERDA or high-energy HI-ERDA applications have been reported since the late 1980s. For example, Mosbah et al. successfully proposed the use of ERDA in transmission geometry to measure the water content of melt inclusions trapped in minerals. Their first published data concerned inclusions from Pantelleria, San Pietro, and Guadeloupe: water contents ranged between 3.4 and 11.8 wt% and agreed well with theoretical calculations. Naitoh et al. have studied the reordering of an aluminum-adsorbed silicon surface like $\sqrt{3} \times \sqrt{3}$ Al/Si(111) induced by hydrogen sorption. They found that saturation occurs for a hydrogen coverage of about $1.3 \times 10^{15}$ H cm$^{-2}$. One totally new application for the TOF-ERDA telescope was introduced by Zhang et al. in 2001. For doing stopping force measurements, they installed a movable thin film between the second timing gate and energy detector and could then obtain continuous stopping curves for this film. This idea has now been used in many places for stopping force measurements, and has given better stopping values for the IBA community.

7 CONCLUSION

Three of the most striking characteristics of the ERDA method are its wide usable energy range from 350 keV to 1 GeV, its strong versatility in terms of detection configurations and variants, and with HI-ERDA, the possibility of depth profiling all the sample elements from H to Bi in a single measurement. Besides the fact that it remains a delicate method, ERDA has featured in IBA-related conferences as the most promising and evolving technique for quantitative determination of elemental depth profiles in solids, from hydrogen to medium and even high mass numbers. In this approach, no prior knowledge of the sample is required and good results can be obtained without standard samples. The basic physics of the elastic collision process has made substantial progress since the late 1980s, especially when considering differential cross-section measurements and models or data-processing methods. Moreover, the spectacular development of high-energy HI-ERDA since the beginning of the 1990s must be emphasized. It is based on the strong theoretical and experimental capabilities derived from nuclear physics research (experimental devices, technical procedures, and theoretical models) that have brought a constant source of improvement to ERDA users for materials science applications. More and more IBA laboratories worldwide have developed specific facilities for applying ERDA to various problems in this field. In addition to

(Data reproduced from Ross and Richard, with the kind permission of Plenum Press.)

Different fluences. The $E \times B$ technique is used with a 350-keV incident helium beam.

Ross and Richard have shown that hydrogen depletion is negligible in Si, SiC, and Sc, higher in Be, Si$_3$N$_4$, and TiC, and very high in C.
high-energy HI-ERDA, special TOF-E telescopes have been constructed for laboratories with smaller (1.7–3-MV terminal voltage) tandem accelerators, making this unique analysis technique available to more users.

The different application examples presented and discussed in the above sections constitute a good sample of the use of ERDA.

ERDA is the most practical IBA technique available for profiling hydrogen isotopes in the near-surface region of solids from 100 nm to 10 µm with a depth resolution of 20 nm for conventional ERDA and even 1 nm for HI-ERDA at the surface. The use of resonant nuclear reactions induced by high-energy heavy-ion beams to profile hydrogen seems to be restricted to specific applications and particularly to samples able to support high fluxes of 0.4–0.5-MeV amu$^{-1}$ $^{15}$N ions.$^{(118)}$ A round-robin characterization of ultrathin to thin (1–100 nm) aluminum oxynitride (AINO) films was organized and the participants used different IBA techniques.$^{(60)}$ This paper gives a good overview of the possibilities and limitations of present IBA techniques in the case of thin films. Considering the analytical capabilities of SIMS, it must be noted that besides its excellent depth resolution and its very strong sensitivity, SIMS is a destructive technique and the calibration of the erosion rate of the target under investigation remains difficult. Nevertheless, the technical improvements encountered with the SIMS machines of the last generation tended to enhance the competition between these two methods.

The future of ERDA looks bright. In three decades, it has matured from something new and exciting to a widely used and trusted technique. In the beginning, the technique was utilized in big laboratories mostly concentrating on nuclear physics, but having plenty of useful instruments around. In the next phase, smaller laboratories, which had mostly concentrated on RBS adopted the conventional ERDA technique, but the instrumentation development was still concentrated on bigger institutes that had mostly high-energy heavy beams available. This millennium, the development has again been toward smaller accelerators, but now using HI-ERDA usually with TOF-E detectors. In these laboratories, the use of 5–20-MeV heavy incident beams have replaced, in many applications, the previously intensively used RBS and nuclear reaction analysis (NRA). This development toward lower energies is likely to continue as large tandem accelerators are not constructed anymore and old ones are being dismantled.

It is not difficult to predict that, in the future, accurate ERD analysis will be performed by means of MC-based simulation software capable of handling properly both multiple and plural scattering, and also all the instrumental effects that broaden the energy spectra. With the aid of this type of analysis, the surface depth resolution, and especially the reliability of analysis deeper in the sample, will be pushed to a new level.

7 Application of Isotope Dilution Analysis to Some Multielemental Determinations

Acknowledgments

Abbreviations and Acronyms

References

The measurement of extremely small traces of materials, which cannot be determined by normal analytical techniques, becomes possible and even relatively rapid and simple if the element can be made radioactive by the action of neutrons or charged particles. Nuclear techniques possess exceptional advantages in having extraordinary sensitivity, selectivity in detection and determination, speed and simplicity.

One of the nuclear techniques applied in trace and ultratrace analysis is isotope dilution analysis (IDA) which was first introduced by Hevesy and Hobbie in 1932. The great advantage of the method lies in the fact that it can be used even when the procedure involves loss of material or does not allow a complete separation of the element or compound. The isotope dilution method has found several applications in the determination of geological ages, fission yields and other problems in nuclear physics and chemistry.

Various techniques involved in IDA such as substochiometry, liquid chromatography (LC) and radiometric titration are discussed along with the application of this technique to the estimation of elements in complex matrices as reported in the literature.

1 INTRODUCTION

The measurement of extremely small traces of materials which cannot be determined by normal analytical techniques becomes possible and even relatively simple and rapid if the element can be made radioactive by the action of neutrons or charged particles.

Nuclear techniques possess exceptional advantages in having extraordinary sensitivity in detection and determination, speed and simplicity. The certainty in identification is excellent as it involves half-life measurement, type of disintegration and energy measurement of the emitted radiation, which are unique properties of an isotope. The sensitivity in many cases is as high as $10^{-10}$ g and in special cases it attains $10^{-12}$ g.
Isotopes are elements (nuclides) having the same atomic number and different mass number. They are classified as stable isotopes (SIs) and radioisotopes (RIs). In IDA, a RI is used as the ‘marked’ analyte. It has the same behavior as the analyte and is called a ‘tracer’, ‘spike’ or ‘label’.

One of the nuclear techniques applied in trace and ultratrace analysis is IDA. In the isotope dilution method, the isotopic composition of an element remains constant throughout a series of chemical reactions. A SI may be used instead of a radioactive isotope, in which case the concentration must be determined by mass spectrometry (MS) or by some other appropriate procedure. The great advantage of the method lies in the fact that it can be used even when the procedure involves loss of material or does not allow a complete separation of the element or compound. It is therefore particularly useful in the measurement of rare earths, fission products and complex mixtures of organic or biomedical compounds.

IDA and reverse isotope dilution analysis (RIDA) have found useful applications with SIs and radioactive isotopes. With the development of MS, and the availability of separated SIs and radioactive isotopes, the isotope dilution method has found several applications in the determination of geological ages, fission yields and in other problems in nuclear physics. Accuracies of a few per cent may be obtained for some elements that are present in concentrations as low as parts per billion (ppb) or parts per trillion (ppt).

2 HISTORY

The term IDA was first introduced in 1940 by Rittenburg and Foster. Hevesy and Hobbie\(^1\) first introduced the method for determining traces of lead present in a mineral in about one part in 10\(^6\); lead was measured by adding Ra D and then depositing PbO\(_2\) anodically. Haissinsky\(^2\) used a similar technique for measuring potassium in the presence of other alkali metals. Similarly, \(^35\)S was used to analyze a mixture of benzyl derivatives of sulfides, sulfones and sulfoxides.\(^3\) Other measurements reported in the literature during the initial phases of the development of the method include naphthenaline in coal tar,\(^5\) \(^\gamma\)-hexachlorobenzene,\(^6\) penicillin,\(^7\) vitamin B\(_{12}\) and other organic compounds. In the case of penicillin, the molecule was labelled with \(^13\)C.

A great advantage of IDA is that it does not require complete separation of the analyte from the sample. However, the quantity of the analyte separated from the matrix must be determined using an appropriate method, e.g. by gravimetry or spectrometry. This is a disadvantageous feature of the classical form of IDA.

To overcome this problem, substoichiometric isotope dilution analysis (Subst-ID) was proposed in 1958 by Ruzicka and Stary\(^8\) where only the measurement of radioactivities is required. The procedure is rapid and easy, and effects of interfering substances are lowered.\(^8\)

In 1974, the ‘sub- and superequivalence (SSE) method’ was introduced into IDA.\(^9\) It does not need such a strict reliance on the stability constant as the Subst-ID mentioned above. Various analytical techniques, such as solvent extraction, ion exchange and precipitation, have been employed for the separation.

3 THEORY

3.1 Principle of Isotope Dilution Analysis

The various types of IDA such as classical IDA, Subst-ID and sub- and superequivalence isotope dilution analysis (SSEIDA) are explained below using mathematical equations. Their characteristics are also explained.

3.1.1 Classical Isotope Dilution Analysis

In this method, an unknown amount (\(x\) ) of analyte in the sample is spiked with a RI (\(A\) = radioactivity; weight is negligible compared with the analyte in the sample). The specific activity of this analyte is \(S_x = A/x\). To the sample, a known amount (\(y\) ) of the analyte is added, so the specific activity of the mixture becomes \(S_{x+y} = A/(x+y)\). An appropriate amount of reagent which reacts with the analyte is added next, and the pure product is separated. To remove any impurity from the matrix, purification must be carried out repeatedly. After that, the weight (\(m_{x+y}\) ) and the radioactivity (\(A_{x+y}\) ) of the product are measured. As the specific activity before and after the separation does not change, we have Equation (1):

\[
\frac{A}{x+y} = \frac{a_{x+y}}{m_{x+y}} \quad (1)
\]

The unknown quantity \(x\) to be determined is calculated from Equation (2):

\[
x = \frac{Am_{x+y}}{a_{x+y}-y} \quad (2)
\]

When the sample contains other components having properties similar to the analyte, it is difficult to obtain complete (100%) recovery of the pure analyte. In such a case, a yield correction would be made in the conventional analysis. However, this correction is not needed in IDA because only the specific activity needs to be known, as shown in the above equations. Therefore, complete separation and recovery are not required and, as a result, repeated purification steps may be made.
to remove impurities. This is the major advantage of IDA. The weight $m_{x+y}$ of the pure separated analyte must be determined by an appropriate method; however, this operation is troublesome and time-consuming. This situation is improved by Subst-IDA.

### 3.1.2 Substoichiometric Isotope Dilution Analysis

In this method, two samples containing an unknown amount ($x$) of the analyte are spiked ($S_x = A/x$) as in classical IDA, and standard solutions containing known amounts ($y, 3y$) of the analyte are added to them. The specific activities of the diluted solutions become $S_{x+y} = A/(x + y)$ and $S_{x+3y} = A/(x + 3y)$. To each, substoichiometric amounts ($M$) of the reagent are added, then the products are separated from unreacted species. Assuming that the quantities ($m_{x+y}, m_{x+3y}$) separated from each sample are the same, namely $m_{x+y} = m_{x+3y} = m$, as the reagent used reacted quantitatively with the reactants, and the radioactivities obtained as $a_{x+y}, a_{x+3y}$, Equations (3) and (4) hold good as the specific activity does not change before and after the separation:

$$\frac{A}{x+y} = \frac{a_{x+y}}{m} \quad (3)$$

$$\frac{A}{x+3y} = \frac{a_{x+3y}}{m} \quad (4)$$

From these equations, we obtain Equation (5):

$$x = \frac{y(3a_{x+3y} - a_{x+y})}{a_{x+y} - a_{x+3y}} \quad (5)$$

Equation (5) shows that $x$ is obtained from the radioactivity without measurement of the weight $m$. This is a major advantage of Subst-IDA. Another point is that the amount of reagent used is substoichiometric compared with the quantity of the analyte and this leads to a decrease in consumption of the reagent by the interfering substances which react with reagent in the same way as the analyte, resulting in improvements in accuracy, precision and sensitivity.

The reagent must react with the analyte almost completely (nearly 100%) and be separated completely if the assumption $m_{x+y} = m_{x+2y}$ is to hold good. For this purpose, the stability constant of the product analyte and the reagent must be sufficiently large. Not many reagents satisfy this condition. This is a disadvantage of Subst-IDA, and to overcome this problem, SSEIDA was proposed.

### 3.1.3 Sub- and Superequivalence Isotope Dilution Analysis

The sample containing an unknown amount ($x$) of the spiked analyte ($A =$ radioactivity, weight is negligible compared with $x$) is placed in each test tube in the first series. They are isotopically diluted by the addition of regularly increasing known amounts $iy$ ($i = 0, 1, 2, \ldots$) of the analyte so that their specific activities become $A/(x + iy)$. In the second series, $k$ times the unknown amount of the first series is placed in each test tube ($kA =$ radioactivity, $kx =$ amount of analyte); they are not isotopically diluted. All solutions in both series are brought to the same volume and same acidity by adding the appropriate amount of solvent.

A definite amount of the reagents is added to each of them. The quantity of reagent is not always necessarily substoichiometric and is allowed to be larger (superequivalent) than that of the analyte. After the separation of the products (first series, $m_{x+iy}$; and second series, $m_{kx}$), their radioactivities are measured (first series, $a_{x+iy}$; second series, $a_{kx}$). As the specific activities do not change before and after the separation, we have Equations (6) and (7):

$$\frac{A}{x+iy} = \frac{a_{x+iy}}{m_{x+iy}} \quad (6)$$

$$\frac{kA}{kx} = \frac{a_{kx}}{m_{kx}} \quad (7)$$

for the first and second series, respectively. From these equations, we obtain Equation (8):

$$\frac{a_{kx}}{a_{x+iy}} = \left( \frac{m_{kx}}{m_{x+iy}} \right) \left( \frac{1}{k} \right) + \frac{m_{kx}}{m_{x+iy}} \quad (8)$$

The quantities $m_{x+iy}$ and $m_{kx}$ generally depend on the concentration of the analyte in the solution, namely $(x + iy)/V$ and $kx/V$. However, if one sample ($i$th increment) in the first series has the same concentration (isoconcentration point) of the analyte as that in the second series, the degree of reaction with the reagent and the degree of separation must be the same. This means that Equation (9) holds:

$$m_{x+iy} = m_{kx} \quad (9)$$

In this special case (at the isoconcentration point), Equation (10) is derived from Equations (6) and (7):

$$\frac{a_{kx}}{a_{x+iy}} = k \quad (10)$$

Substituting Equations (9) and (10) into Equation (8), Equation (11) is obtained:

$$x = jy(k - 1) \quad (11)$$

Thus, to determine $x$, it is necessary to find $j$. The value $j$ is virtual and does not necessarily have to be an integer (the value of $x$ is obtained by a graphical method). The number of samples of the second series is not necessarily...
large, but several samples are generally used to obtain a reliable value by averaging.

As SSEIDA does not impose strict conditions on the reactivity and the quantity of the reagent, it has a wide range of choice of reagents compared with Subst-IDA. On the other hand, determination by classic IDA and Subst-IDA is possible using one or two samples (except for the multiple method), but more than four samples are necessary in SSEIDA to find the isoconcentration point. Therefore, this method demands more time and effort, and is not suitable for the analysis of small quantities of samples.

As is known from Equations (6) and (7), the effect of interfering substances is not negligible because their quantities in the matrix are different in the first and second series. Apart from this disadvantage, SSEIDA seems to be an excellent method when sensitive, precise and accurate determination by Subst-IDA is difficult.

3.1.4 Stable Isotope Dilution Analysis

The principle of stable IDA is almost the same as that of radioisotope dilution analysis (radio-IDA). The difference is that radio-IDA makes use of the change of specific activity but stable IDA must depend on the change in the isotope ratio. A mass spectrometer is the only instrument sensitive enough to measure the isotope ratio, so this method is also called isotope dilution mass spectrometry (IDMS).

Two isotopes (1 and 2) are selected from the various isotopes comprising the analyte to monitor the isotope ratio. Their isotopic abundance in a sample containing an unknown amount (x) of the analyte are taken as $\theta_{x(1)}$, $\theta_{x(2)}$. To the sample, a known amount (y) of the analyte having an enriched SI of composition different from that of the sample is added, where the isotopic abundances of the SI are $\theta_{y(1)}$, $\theta_{y(2)}$, respectively. The isotope ratio, $R_{x+y}$, of 1 and 2 in the mixture after mixing with the diluent is calculated using Equation (12):

$$R_{x+y} = \frac{x\theta_{x(1)} + y\theta_{y(1)}}{x\theta_{x(2)} + y\theta_{y(2)}}$$  \hspace{1cm} (12)$$

From this equation, we obtain Equation (13):

$$x = \left[ \frac{\theta_{y(1)} - R_{x+y}\theta_{x(2)}}{R_{x+y}\theta_{x(2)} - \theta_{x(1)}} \right]y$$  \hspace{1cm} (13)$$

As $\theta_{x(1)}$, $\theta_{x(2)}$, $\theta_{y(1)}$, $\theta_{y(2)}$ and $R_{x+y} = \left[ m_{x+y}, \theta_{x+y(1)} \right] / \left[ m_{x+y}, \theta_{x+y(2)} \right]$ of product $m_{x+y}$, which is separated from matrix elements, are determined by MS and y is known, x is calculated from Equation (13).

3.2 Instruments Used

3.2.1 Radioisotope Dilution Analysis

Some radio-IDA needs to use RIs, so instruments for measuring radioactivity are necessary. An appropriate instrument is selected depending on the kind and energy of radiation.

For example, a NaI(Tl) scintillation counter is commonly used to measure γ-rays from RIs such as $^{125}$I and a liquid scintillation counter is used for low-energy β-rays from $^3$H, $^{14}$C, etc. A Geiger–Müller counter is used for high-energy β-rays from $^{204}$Tl etc. A high-resolution HPGe semiconductor detector is able to measure γ-rays of various energies at the same time.

3.2.2 Stable Isotope Dilution Analysis

Mass spectrometers are used in stable IDA to measure isotopic ratios. The instrument mainly consist of three parts, for ionization, separation of ions and detection. For ionization, glow discharge, inductively coupled plasma (ICP) and corona discharge are suitable for solid, liquid and gaseous samples. MS combined with gas chromatography (GC) and LC are useful for preliminary separation and concentration of the analyte.

An example of Subst-IDA for the determination of iodine in common salts using $^{131}$I as tracer is given below.

About 1 g, accurately weighed, of powdered salt sample was dissolved in 25 mL of doubly distilled water. Carrier solution (10–60 μg of iodide as NaI) and a suitable aliquot of $^{131}$I were added and the whole system was warmed to about 50 °C. After cooling, 5 mL of tartaric acid and 2 mL of potassium iodate solutions were added. This mixture acts as a mild oxidizing agent and oxidizes only $\text{I}^-$ to $\text{I}_2$ and leaves chloride as such. Initially an attempt to use H$_2$SO$_4$ instead of tartaric acid was made, but this resulted in large-scale oxidation of chloride, causing interference in the substoichiometric stage. The iodine liberator was immediately extracted into CCl$_4$. To the organic phase 0.1 mL of AgNO$_3$ solution (in substoichiometric amount) and 10 mL water were added. Typically about 15 μg or its integral multiple amounts of Ag were added for substoichiometric extraction. This gave approximately 80% extraction. After thorough mixing, a colloidal solution of AgI was formed in the aqueous phase, to which, after separation, 1 mL of sodium thiosulfate solution was added. This resulted in the formation of NaI in the aqueous phase, which was then counted on a 1.75 \times 2.00 in a well-type NaI(Tl) detector.

When analyzing actual samples of common salts, however, a standard solution of NaCl with a known concentration of iodine (as NaI) was simultaneously analyzed according to the standard procedure. Finally, the specific activities of the standard and the sample
aliquots were compared and the concentration of iodine was calculated.

In order to ascertain the accuracy and precision of the method, several suitable mixtures of NaCl and NaI were analyzed. To a solution of nearly 1 g of NaCl, an aqueous solution containing 3–60 \( \mu \text{g} \) of NaI was added and its iodine content was determined.

Iodine is important as an essential trace element for humans, and its deficiency leads to goiter, a prominent disorder of the thyroid gland.\(^{10,11}\) The important sources of iodine are foodstuffs and beverages that contain seafoods and common salt. In order to circumvent the deficiency of iodine in many parts of the world, several countries have launched a program of dietary supplementation. Even such programs have not always been successful in countering goiter in some countries.\(^{12}\)

In India, the consumption of seafood is very low and common salt is the only source of iodine. The Government of India has now launched a program for the consumption of iodized salts by the general public. Iodine has been determined by other methods also.\(^{13–15}\)

4 STATISTICAL EVALUATION OF THE METHOD WITH RESPECT TO ACCURACY, PRECISION AND SENSITIVITY OF ISOTOPE DILUTION ANALYSIS

4.1 Factors Affecting Precision

The precision of the weighing of the separated analyte is important. However, with Subst-IDA weighing is not required.

Errors in counting radioactivity also affect precision. The measurement should last long enough to lower the error \( E \) to below 1\% according to equation (14):

\[
T = \frac{10000}{E^2r}
\]  

(14)

where \( T \) = period of measurement and \( r \) = counting rate.

4.2 Factors Affecting Accuracy

The tracer and carrier (diluent) must behave in the same manner as the analyte in the sample in order to obtain a constant specific activity throughout the procedure. For this purpose, properties such as valency state of the element and the kind of reagent must be made uniform at an early stage of analysis. Isotopic equilibrium between the tracer and the analyte must be complete.

Loss of analyte (in unknown amount) may be caused during dissolution by adsorption on the container wall, vaporization, etc. When an unknown amount of an analyte is lost before dilution with the tracer, it strongly affects the accuracy of the method. Therefore, it is desirable to mix the tracer and diluent with the sample in the earliest stages of the operation. Loss after exchange does not affect the accuracy.

In each analysis, a simple clean room is desirable to prevent contamination from the reagents, apparatus, atmosphere, etc. which affects the accuracy. It must be ensured that the radioactivity comes from only one type of nuclide, i.e. the sample is radiochemically pure. When there is another element which emits radiation similar to that of the tracer in the sample, it affects the accuracy. In these cases, the tracer should be purified.

4.3 Factors Affecting Sensitivity

The volume of the reaction mixture should be minimized to increase the sensitivity. The presence of interfering ions affects the sensitivity, but the effect is less in Subst-IDA and SSEIDA, so the sensitivity of these methods is higher than that of classical IDA.

5 LIMITATIONS OF THE METHOD

The use of the proposed method for the determination of amounts of metals larger than 1 \( \mu \)g is not advantageous, because physicochemical analytical methods may be used whose precision is, under these conditions, better than the precision of radiometric methods, which is controlled by the statistical character of the radioactive decay. The sensitivity of the method is limited by two factors: (a) the organic reagent employed cannot be diluted infinitely and (b) at present, RIs of sufficiently high specific activity are not at hand for all cases. The latter limitation has been solved to a certain extent by the development of procedures for the preparation of carrier-free RIs.

6 APPLICATION OF ISOTOPE DILUTION ANALYSIS TO THE DETERMINATION OF SOME REPRESENTATIVE ELEMENTS

6.1 Boron

A method has been described for determining traces of boron in silicon.\(^{16}\) The sample was dissolved in aqueous sodium hydroxide in the presence of \(^{10}\text{B} \) tracer, and boron was separated by modification of Morrison and Rupp’s method of electrolysis through a cation-exchange membrane. Boron was finally determined by making isotope dilution measurements with a mass spectrometer with a thermal ionization source. The method has the advantage that quantitative separation of boron was not
necessary. Amounts of boron down to 0.001 µg can be
determined to within ±30%.

6.2 Carbon
The sensitivity and precision of field-desorption MS
are greatly improved by using an isotopically labelled
standard compound and averaging the m/z values for
a large number (e.g. 100 or 210) of spectral scans.(17)
Cationization involves the production of molecular ions
with enhanced m/z values, e.g. when a mixture of glucose,
[13C] glucose and NaI was dissolved in water, and
the solution was applied to a high-temperature field-
desorption emitter, the spectrum contained peaks for the
species (M + Na)⁺. The use of such peaks, with correction
for [13C] glucose in the nominally unlabelled glucose,
permits the determination of glucose with a mean error
of ±7%. The method is considered to show promise for
biomedical analysis.

Small amounts of carbon in metals have been deter-
mined by the isotope dilution method by using an
omegatron.(18) From 0.4 ppm to 6% of carbon in steel,
iron, copper, tin, nickel, tungsten or molybdenum or in
tungsten carbide was determined by heating the sample
(in the form of a thin ribbon) at 1400 K in an atmosphere
containing a known concentration of 13CO. After 3 h the
concentration of 13CO and 12CO in this atmosphere were
determined by MS using a dynamic mass spectrometer
(omegatron). The coefficients of variation were <10%.

A method utilizing IDMS has been developed for
the determination of carbon in sodium.(19) The details
of the method are described for the determination of
elemental carbon employing Van Slyke oxidation,
although, by choice of spike material, other forms of
carbon may be determined. Accuracy and precision in
the ranges of 50 ± 10 to 150 ± 25 µg of carbon have been
demonstrated. The determination was not affected by the
loss of generated carbon dioxide or by contamination
from any source except carbon.

6.3 Nitrogen
The method described has been applied to the determi-
nation of nitrogen in Nb, W, Mo, La, Ce, Re, Fe, Cr
and Ni.(20) It is based on MS measurement of changes
(effected by dilution with the nitrogen from the sample)
in the isotopic composition of 15N used as an indicator.
Nb was used as carrier for the indicator (forming nitrides)
for improving the isotopic exchange between indicator
and sample. The sensitivity was 1 ppm and the precision
was 3% for 5 g samples containing 10 ppm of nitrogen.

6.4 Oxygen
Oxygen has been determined in iron and steel by a modi-
fied isotope dilution technique.(21) Previous discrepancies
in the determination of oxygen in steel by an isotope
dilution and vacuum fusion technique were traced to
adsorption of C18O on deposits in the furnace. By treat-
ning the specimen at dull-red heat with a measured volume
of oxygen enriched in 18O and allowing it to cool before
lowering it into the graphite crucible, good agreement
was obtained between the two methods.

6.5 Phosphorus
In the method described, 32P-labeled sodium phosphate
was used to determine 10–50 ppm of P in 3–5 g samples
of triuranium octaoxide.(22) The error was <3% and the
reproducibility was satisfactory. The method depends on
the precipitation of the P as molybophosphate, which is
converted into MgNH4PO4 for counting.

The use of the isotope dilution technique to eliminate
problems associated with demands for a high load
capacity in column-coupling capillary isochromatography
was studied.(23) Determinations of phosphate present
in a model mixture and in white wine served for the
evaluation of this approach to quantitative analysis in
isochromatography. A high selectivity of the analysis with
acceptable accuracy and precision of the analysis of
complex ionic mixtures in a short time are obvious
advantages of this approach.

6.6 Sulfur
Adsorbed sulfate in soil was determined by adding a
small quantity of carrier-free 35S as sulfate to a solution
in equilibrium with the soil.(24) The adsorbed sulfate was
calculated using the isotopic dilution law from total added
activity and the activity in the equilibrium solution. Total
added activity and activity in the equilibrium fractions
were determined by suspending soil in water overnight,
adding a solution containing 35S, diluted to an activity
close to 6.7 kBq, shaking the suspension for 2 h and
centrifugation at 9000 rpm for 10 min. One part of the
supernatant was used for liquid scintillation analysis and
mixed with Quick Safe A. The remaining supernatant
was filtered through a 0.2 µm membrane filter and sulfate
was determined using a Dionex 2000i ion chromatograph
equipped with a AS4 anion-exchange separation column.
Phosphate-extractable sulfate was extracted with 10 mM
calcium dihydrogenphosphate. Part of the supernatant
was obtained between the two methods.

6.7 Argon
Radiogenic Ar was determined in rock samples by the
method of isotope dilution with an AlCl3 standard
6.8 Potassium

Small amounts of K have been determined by IDA, involving an exhaustive chemical procedure. A method for the determination of K in minerals difficult to decompose by chemical means is described. Procedures for beryl and tourmaline are given. A method has also been described for the mass spectrometric determination of K in minerals containing <1% of K. The results agree reasonably well with those obtained by chemical methods.

6.9 Calcium

The IDMS determination of low concentrations of Ca in minerals has been discussed. The IDMS determination of low concentrations of Ca in minerals has been discussed. The IDMS determination of low concentrations of Ca in minerals has been discussed. The IDMS determination of low concentrations of Ca in minerals has been discussed. The IDMS determination of low concentrations of Ca in minerals has been discussed. The IDMS determination of low concentrations of Ca in minerals has been discussed. The IDMS determination of low concentrations of Ca in minerals has been discussed.

6.10 Chromium

A method has been described for the determination of chromium and its enriched SI in human urine by IDMS. A volatile chelate was formed using trifluoroacetylacetone (TFA) and the fragment ions corresponding to Cr(TFA)2+ in the m/z 356–360 region were monitored. The chelate was thermally stable and exhibited no memory effects when the isotope ratios changed. The detection limit for the method was 0.03 ng g⁻¹ of Cr and the accuracy was verified using certified reference materials (CRMs) and by an independent method. The method was highly specific for chromium, owing to the combined properties of the chelating agent, chromatographic column and mass-specific detector. In addition to total chromium determinations, the method can also be used to quantitate enriched SIs of chromium used as metabolic tags in tracer experiments in human nutrition studies.

6.11 Iron

IDA by ion exchange has been used for the determination of traces of iron. A theoretical evaluation of this method is given, from which the conditions for the determination of a number of metals can be predicted. The selectivity of the method was further increased by the use of masking and precipitating agents. The proposed method has been verified by the determination of iron using EDTA and Dowex 50 cation exchanger. The average precision of mean values for amounts of 10⁻⁷ g of Fe per 5 mL was 1.2%, for amounts of 10⁻⁸ g of Fe per 5 mL it was 4.0% and for amounts of 10⁻⁹ g of Fe per 5 mL it was 4.1%. Even large excesses of many metals did not interfere in the analysis. The method has been applied to the analysis of NaI(Tl) crystals. The procedure which has been developed is very simple, and is far more sensitive than colorimetry, activation analysis or other methods used up to now for determining traces of iron.

6.12 Cobalt

IDA has been combined with solvent extraction and spectrophotometry to produce an effective general method for the determination of constituents that will not extract quantitatively. Combining isotope dilution with extraction of the cobalt–2-nitroso-1-naphthol complex into chloroform resulted in an accurate and reliable method for the determination of small amounts of cobalt in alloys of high copper content and in ingot irons. ⁶⁰Co was used as a radioactive tracer.

An isotope dilution method for the determination of cobalt employing ⁶⁰Co as the tracer and a spectrophotometric procedure based on the extraction of cobalt thiocyanate with methyl isobutyl ketone (MIBK) has
been developed. The extraction was carried out under neutral or slightly basic pH conditions and this made the procedure virtually specific for cobalt. The method was suitable for the determination of cobalt at concentrations from a few parts per million upwards in biological materials, vitamin B12, salts, metals, etc. When a well-type scintillation detector was used for measuring the radiation of $^{60}$Co in liquid samples, the procedure was relatively simple and rapid. The results obtained in testing the behavior of a number of metals and the various stages of the extraction of cobalt thiocyanate with MIBK in the presence of $^{60}$Co as tracer are also presented.

6.13 Copper

Copper has been determined in serum samples by radio-IDA and incomplete extraction. On decomposition of serum from a venous blood sample, Cu was labeled with $^{64}$Cu. Dithizone in CCl$_4$ was used for extracting Cu at substoichiometric levels. The original Cu concentration was calculated from Ruzicka’s equation. The method is compared with a colorimetric method.

6.14 Zinc

A new separation method using ion exchange based on complexation in a resin matrix has been used for the substoichiometric determination of Zn by the isotope dilution method using a chelating agent-loaded resin. A resin loaded with 8-quinolinol-5-sulfonic acid was also shown to be applicable to the selective preconcentration of chalcophile elements in natural water samples. An additional advantage of this resin was that the ion-exchange capacity can be varied according to the desired purpose and therefore substoichiometric separation may be achieved. The possibility of the determination of Zn with substoichiometric amounts of 8-quinolinol-5-sulfonic acid was investigated.

The comparative extractability of Zn with potassium salts of ethyl, propyl, butyl, pentyl and benzyl xanthates in the pH range 3.5–9.0 into chloroform has been studied, employing a sensitive and rapid substoichiometric radiochemical method. The extent of reproducibility was tested in each case. The effect of associated ions on the extraction was studied. The amount of Zn present in the standard solutions was determined employing each xanthate separately. The Zn content present in geological water samples in and around Tirupati was determined by the method developed and compared with the values obtained by atomic absorption spectroscopy (AAS).

6.15 Arsenic

Arsenic has been determined in biological and environmental standard reference materials (SRMs) by substoichiometric solvent extraction using toluene-3,4-dithiol in benzene. A radiochemical solvent extraction procedure has been developed for the determination of As(III) using $^{75}$As tracer. It is based on the complexation of As(III) with toluene-3,4-dithiol at pH 2 and subsequent extraction in benzene. The effects of various parameters such as pH, time of equilibration, nature of solvent, quantitative character and interferences were studied. The method has been further developed into Subst-IDA for the determination of As at <1 mg levels and employed for the analysis of several environmental and biological SRMs from the National Institute of Standards and Technology (NIST) (USA), the International Atomic Energy Agency (IAEA) (Vienna) and NIES (Japan).

6.16 Selenium

Selenium has been determined in plant materials by a fluorimetric method employing $^{75}$Se. An exhaustive chemical procedure is described. A 0.05% solution of purified naphthalene-2,3-diamine in 0.1 M HCl (0.5 mL) was employed for the fluorimetric method. The fluorescence was compared against a reagent blank. The isotope dilution results were used to correct for losses during the combustion and extraction. Of 20 metal ions tested, serious interference was observed from Cr$^{3+}$, Sb$^{3+}$ and Sn$^{4+}$. The standard deviation (SD) for the determination of 0.2 µg of Se was 0.04 µg.

The determination of Se by the SSE method of IDA involves the extraction of a test solution of Se labeled with $^{75}$Se. Sodiumdiethyldithiocarbamate was used as reagent and CCl$_4$ as a solvent. The activity was counted on an NaI(Tl) detector. The Se concentration was calculated from a calibration graph of concentration against the ratio $A$ to $A'$ where $A$ = activity in the organic phase and $A'$ = repeated measurement in a fresh aliquot. For 1.92 ppm of Se, the SD was 0.1371 ppm.

A method is described for the determination of 10$^{-2}$ ppm levels of Se in organic samples. The method consists of a micromodification of the spectrophotometric method employing 3,3'-diaminobenzidine as reagent for extracting selenium(IV), and incorporates an isotope dilution technique to compensate for the unavoidable losses that occur during the course of the determination of Se.

6.17 Silver

Isotope dilution electroanalysis has been used for the determination of silver at microgram levels. The method consists in electrolysis at a controlled potential with a silver-wire cathode and a platinum wire anode and the measurement of the specific activity of the Ag deposited on the cathode. Two microelectrolysis cells were connected in series, one containing an amount
of inactive Ag (x) plus a known amount of $^{110}\text{Ag}$ (y) and the other containing the same amount (y) of $^{110}\text{Ag}$. In the presence of Cu$^{2+}$, Ni$^{2+}$ and Cd$^{2+}$, Ag may be determined in the range $10^{-3}$ to $10^{-6}$ g mL$^{-1}$ of electrolyte with a coefficient of variation of 2.3% at the $10^{-5}$ g mL$^{-1}$ level.

### 6.18 Cadmium

Cadmium has been determined in SRMs.$^{(41)}$ The method involves four polyethylene samples with nominal Cd contents from 40 to 400 ppm, which were supplied as small wire cuts each of about 10 mg. Each sample was mixed for 1 h and bottled in 30 g units. Homogeneity was tested by taking 15 pieces of 60–250 µg from each of the four bottles and analyzing them by solid-sampling Zeeman-corrected AAS, with measurement at 326.1 nm. These results were tested statistically. Samples VDA-001, -002 and -003 gave normally distributed results. The fourth and homogeneity factors and minimum representative sample weights (13–27 mg) were calculated. The fourth sample, VDA-004, was not normally distributed, with sample weights (13–27 mg) were calculated. The fourth sample, VDA-004, was not normally distributed, with some microheterogeneity, but could still be used if sample contents from 40 to 400 ppm, which were supplied as small wire cuts each of about 10 mg. Each sample was mixed for 1 h and bottled in 30 g units. Homogeneity was tested by taking 15 pieces of 60–250 µg from each of the four bottles and analyzing them by solid-sampling Zeeman-corrected AAS, with measurement at 326.1 nm. These results were tested statistically. Samples VDA-001, -002 and -003 gave normally distributed results. The fourth and homogeneity factors and minimum representative sample weights (13–27 mg) were calculated. The fourth sample, VDA-004, was not normally distributed, with sample weights (13–27 mg) were calculated. The fourth sample, VDA-004, was not normally distributed, with some microheterogeneity, but could still be used if sample weights (13–27 mg) were calculated.

### 6.20 Antimony

A rapid and selective substoichiometric radiochemical method has been developed for the determination of microgram amounts of antimony employing potassium ethyl xanthate as a reagent and chloroform as an extractant from sulfuric acid medium.$^{(44)}$ The effect of associated ions on the extraction was studied. The method developed was successfully applied to determine the antimony content in standard solutions and synthetic mixture with an average error of ±2.07%.

### 6.21 Tellurium

A radiometric method based on redox substoichiometry has been developed for the determination of tellurium.$^{(45)}$ The oxidation of tellurium(IV) to tellurium(VI) with potassium dichromate was employed as the substoichio-
metric reaction, followed by tributyl phosphate extraction of the unreacted tellurium(IV) for substoichiometric isolation. The oxidation of tellurium(VI) with dichromate under the substoichiometric conditions was incomplete. The chemical yield of tellurium(VI) produced by the oxidation of tellurium(IV) with dichromate was 83%. It was found that a tellurium content of 50–160 µg could be determined with an accuracy of ±1.3% by means of the comparison method.

### 6.22 Iodine

A Subst-IDA method was developed for the determination of iodine in different brands of common salt.$^{(46)}$ An aqueous salt solution containing $^{131}\text{I}$ tracer and NaI as carrier was oxidized by tartaric acid and KIO$_3$ and the liberated iodine was extracted with CCl$_4$. To the extract an aqueous solution of AgNO$_3$ was added in substoichiometric amount to obtain a colloidal solution of AgI. On adding sodium thiosulfate solution, the NaI so formed passed into aqueous solution, which was then counted. Several different brands of salt were analyzed. The method was especially suitable for the determination of microgram amounts of iodide in the presence of excess of chloride.

### 6.23 Lanthanum

The Subst-IDA method has been used for the determination of La in environmental samples using cupferron in chloroform.$^{(47)}$ Dried powder was fused with sodium peroxide and 99.9% scandium oxide as holdback carrier. The fusion mixture was allowed to melt with occasional stirring, the resulting cake was cooled in H$_2$O$_2$ and 6 M HCl before dilution with water. The $^{140}$La tracer was treated with La carrier solution, water and 0.02 M aqueous cupferron. Ammonium buffer of pH 9.0 was added...
and the resulting solution was shaken with chloroform for 2 min. After equilibration, a brown-red complex was formed with clear phase separation. A portion of the organic and aqueous phases were counted at the 487 and 1596 MeV photopeaks of $^{140}$La using an NaI(Tl) well-type detector in conjunction with a multichannel analyzer (MCA). The calibration graphs were linear for 22–550 ng and 1.75–44 µg of La. The method was applied substoichiometrically to four cement dust particulate samples and SRMs of environmental importance; the relative SD was <8%. Interference masking and elimination methods are discussed.

6.24 Hafnium

Hafnium has been determined in Ze-4 and Ze-6 zirconium metal standards by stable IDA. Hf values obtained for Ze-4 and Ze-6 standards were 77.4 ± 3.9 (tentative) and 166 ± 17 ppm, respectively.

Hafnium has been separated from zirconium by a chromatographic method and determined by IDA. The method is based on the different stabilities of the sulfate complexes. The best separation was obtained by using 0.65 N H$_2$SO$_4$ for washing the cationic column. With 0.7 N H$_2$SO$_4$ the separation was significantly quicker, although not quantitative, but this did not interfere with the method of isotope dilution. The relative error was <1% of Hf in mixture containing approximately 10% of Hf, but higher if the Hf concentration was <3%. The method was used for the determination of Hf in eudialyte and Zr and also in mixed oxides of Zr and Hf of various concentrations.

6.25 Tungsten

An isotope dilution procedure using $^{185}$W for the determination of W in high-alloy steels has been described. Tungsten was determined spectrophotometrically with quinol in H$_2$SO$_4$ after homogeneous precipitation from HNO$_3$–H$_2$O$_2$. No further chemical separation was required for Mo–V–W steels, but for steels containing Nb, Ta and/or Ti, chemical separation of the elements that would interfere with subsequent spectrophotometric determination was necessary. The method was successfully tested on a number of National Bureau of Standards (NBS) steels to which various amounts of Ta and Ti were added.

6.26 Rhenium

Rhenium has been determined by a surface ionization isotope dilution method. Down to 1 µg of Re can be determined by MS by heating (at 2200 °C) a tungsten filament on which the metal has been deposited. Re in 10 mg samples of Re–W alloys (3–25% of Re) has been determined by an isotope dilution method (with use of $^{187}$Re) with a SD of ±2%.

A radiotracer method has been used for the determination of Re. Radiometric correction and interpolation methods have been suggested for rhenium determination using a $^{188}$Re (16.9 h) radiotracer. The radioactive isotope was obtained in an $^{188}$Re generator consisting of a glass column filled with aluminum oxide with a parent isotope $^{188}$W (69.4 days) firmly adsorbed. The isotope $^{188}$Re formed was eluted from the generator with a 0.9% solution of sodium chloride. Isotopic equilibrium among stable and radioactive rhenium (in the form of perrhenate ions) was obtained just after mixing the two solutions. A scintillation detector with a NaI crystal was used for γ-counting.

Rhenium has been extracted with a tetraphenylphosphonium complex into dichloroethane. Liquid scintillation counting was used. By this method, 1–100 µg of rhenium(VII) in the analyzed sample was determined. The relative SD was 0.05–0.09% over the whole concentration range.

6.27 Gold

Gold has been determined by radioactivation analysis accompanied by the isotope dilution method. The sample (containing $M_x$ of the element to be determined) and the standard (containing $M_y$) were irradiated under identical conditions and then each was mixed with a large amount of carrier, an aliquot was separated and their activities $A_x$ and $A_y$ were measured. The value of $M_x$ is expressed by $M_x = M_y A_x / A_y$. This relationship has been exemplified by the determination of Au (0.03–3.4 ppm) in metallic Cu with rhodamine B (CI Basic Violet 10) solution as extracting agent.

6.28 Mercury

IDA by solvent extraction has been employed for the highly selective determination of trace amounts of Hg. Mercury has been determined in amounts of $10^{-8}$–$10^{-7}$ g mL$^{-1}$ with an average precision of ±0.5% and in amounts of $10^{-8}$–$10^{-9}$ g mL$^{-1}$ with an average precision of ±2.5%. The determination of smaller amounts of mercury was subject to large errors because of the lower specific activity of the radiomercury employed. In the analysis, even significant excesses of metals which also form extractable complexes with dithizone do not interfere. The method is very rapid and simple, because it consists of a single extraction of the analyzed solution and measurement of the activity of the extract. The procedure developed is far more precise and sensitive than the colorimetric method.

A new principle for the substoichiometric determination of traces of Hg by IDA has been reported. The
method was based on the dithizone–carbon tetrachloride extraction of Hg from the test solution (e.g. a solution of an ore or a mineral water). The necessity for determining the chemical yield was avoided. The main advantage of the isotope dilution method is the use of low activities.

Malonic anilide has been employed for the substoichiometric extraction of Hg into a mixture of ether and MIBK and for the subsequent determinations in industrial effluents from the Durgapur area, W.B., India.\(^{(56)}\)

A radiometric method based on Subst-IDA has been developed for the determination of trace amounts of Hg using \(\alpha\)-thiopicolin-o-anisylamide as a substoichiometric reagent.\(^{(57)}\) A preconcentration procedure has also been developed based on the adsorption of Hg(II) as a dithizone complex on microcrystalline naphthalene which, when used in conjunction with the proposed radiometric method, enhances its sensitivity and selectivity. As little as 0.2 \(\mu\)g of Hg could be determined in an aqueous phase of 80 mL. The method has been successfully applied to the determination of trace amounts of Hg in city waste incineration ash, zinc metal and cadmium oxide samples.

6.29 Thallium

Thallium has been determined by SSEIDA.\(^{(58)}\) The general method has been applied to the determination of Tl. A constant substoichiometric amount of EDTA was used, and the unchelated Tl\(^{3+}\) was removed by precipitation with aqueous ammonia before an equal volume of the solution was removed for counting. Common anions did not interfere, and interfering cations were eliminated by extracting Tl(III) from 6 M HCl into diethyl ether.

Thallium has been determined using brilliant green by SSEIDA.\(^{(59)}\) The 1:1 complex between TICl\(_4\) and the brilliant green (I) cation was extracted into benzene; this avoided the need for large excess of the reagent and yielded a stable colour with a high \(E\) value. In the subequivalence test, the aqueous medium, containing radioactive plus inactive Tl (carrier), was made 2.5 M in HCl, I was added in substoichiometric amount and the extraction was carried out for 9 min. The benzene extract was evaporated and the residue was counted with a Geiger–Müller tube. In the superequivalence variant, twice as much radioactive (but no inactive) Tl and more I was used. The amount of active Tl was found from the point of intersection of isotope dilution curves. For 0.5–105 \(\mu\)g of active Tl(III), the errors ranged from ±1.2% to 2.3%. Preliminary extraction of Tl into diethyl ether from 6 M HCl medium and washing the extract with 3 M HCl prevented interference from Fe(III), Ga(III) and In(III). Interference from Au(III) and Sb(V) was avoided by reducing these with metallic Cu before extraction.

Sulfate, nitrate and acetate interfered in the formation of the Tl complex.

6.30 Lead

Ultramicro amounts of lead have been determined by IDMS.\(^{(60)}\) After isotopic equilibration with approximately 0.5 \(\mu\)g of \(^{208}\)Pb, the sample, e.g. pure water or snow (20–100 g), was mixed with silica gel (13 \(\mu\)g) and \(\text{H}_3\text{PO}_4\) (127 \(\mu\)g) as stabilizing agents, and part of the mixture was loaded on to a rhenium filament for MS. The Pb concentration of the sample was calculated from the ratio of \(^{206}\text{Pb}^+\) to \(^{208}\text{Pb}^+\). The coefficient of variation was approximately 3% for several measurements of added \(^{208}\)Pb (0.003–1.8 \(\mu\)g), 3–7% for river water (approximately 0.07 ppb) and 1.3% for mountain snow (0.86 ppb). The instrument produced 1 fA of ion current from each nanogram of added \(^{208}\)Pb\(^+\), the detection limit being 0.1 aA. The method was also applicable to the analysis of reagents, e.g. ammonia solution, hydrochloric acid and perchloric acid.

The application of displacement and exchange reactions in IDA of Pb has been studied.\(^{(61)}\) The efficiency of separation of metal ions combining a displacement or exchange reaction and a liquid–liquid extraction procedure was calculated as a function of parameters such as pH, the ratio of the concentration of reagent and analyte and the ratio of the concentration of reagent and interfering ions. The resulting equations can be used to calculate favorable conditions for multielement IDA.

6.31 Uranium

A procedure and instrumentation for the automatic measurement of isotopic ratios with a double collector magnetic mass spectrometer have been used for U-isotope analysis.\(^{(62)}\) Essentially, measurement was achieved by discriminating in favor of the desired peak plateau for ion current integration during the high-voltage variation. The peak resolution was virtually unaffected by off-set drift in the electronic system. Before each ratio measurement, the off-set values were determined and digitally stored for final compensation when isotopic ratios were calculated with an arithmetic unit.

Traces of uranium have been determined in metallic sodium by IDA and a spectrophotometric method.\(^{(63)}\) Sodium (5 g) was evaporated (within 5 h) at a pressure of 10\(^{-4}\) Torr at 350 °C in a stainless-steel crucible. There was no loss of U (approximately 1 \(\mu\)g) under these conditions. An isotope dilution method was used to determine 0.001–1 ppm of U with the use of an NBS standard isotope. For >1 ppm of U, the U was reduced with Zn amalgam to U(IV), which was determined spectrophotometrically with arsenazo III after extracting

---

\(^{56}\) V. K. Prasad, V. V. Prasad and S. T. S. Srivastava, Talanta, 1975, 22, 1.

Fe(III) with diethyl ether. No interference was caused by the small amount of Fe dissolved from the crucible.

### 6.32 Plutonium

Plutonium has been determined in a NIST SRM by IDA.\(^{64}\) SRM 4351 human lung was acknowledged to be inhomogeneous. The value of a single analysis for \(^{239}\)Pu + \(^{240}\)Pu could lie within a wide range, but the accuracy of the analysis can be corroborated by comparing the corresponding \(^{235}\)Pu/\(^{239}\)Pu + \(^{240}\)Pu or \(^{240}\)Pu/\(^{239}\)Pu values with the relationships between these ratios and the total plutonium concentration. The \(^{238}\)Pu/\(^{239}\)Pu ratio was reported by activity and the \(^{240}\)Pu/\(^{239}\)Pu ratio by atoms in aliquots of the SRM 4351. The data give an experimental insight into the inhomogeneity of the material, augmenting the purely statistical indicators that have existed so far. An intercomparison exercise on \(^{239}\)Pu + \(^{240}\)Pu in SRM 4351 was carried out. The objectives were to evaluate the capabilities of the participating laboratories for Pu measurements in human tissues and to improve the characterization of the \(^{239}\)Pu + \(^{240}\)Pu concentration value for the SRM. The results were published, but the values of \(^{239}\)Pu and of \(^{240}\)Pu as distinct from \(^{239}\)Pu + \(^{240}\)Pu figures were not reported.

### 7 APPLICATION OF ISOTOPE DILUTION ANALYSIS TO SOME MULTIELEMENTAL DETERMINATIONS

IDA has been used for the certification of SRMs.\(^{65}\) Isotope dilution has been applied at the NBS, employing thermal ionization or spark source MS, to determine accurately the concentration of trace elements in natural materials. These techniques have been applied, in conjunction with separation by ion exchange, chelation by resins, electrolytic deposition and chemical extraction. The certification of a range of biological and environmental SRMs, including the contents of Pb and trace elements in water, 15 elements in coal and fly ash, U in bovine liver and Hg in water, is presented.

IDA has been used for the trace analysis of microelectronics relevant heavy metals in high-purity titanium.\(^{66}\) Because titanium is increasingly used in microelectronic devices, an IDMS method has been developed for the reliable determination of traces of U, Th, Cu, Pb, Cd, Cr, Ni and Fe in high-purity titanium primary materials. The measurement of isotope ratios was carried out with a thermal ionization quadrupole mass spectrometer using positive thermal ions formed by a single- or double-filament ion source, except for thorium, where an ICP mass spectrometer was applied. Different separation techniques (ion exchange, chromatography, extraction, electrolytic deposition, coprecipitation) were used for the trace element–matrix separation and for the specific isolation of the trace elements to be determined. The detection limits obtained were U, Th = 0.07, Cu = 1, Cd = 1.7, Ni = 4, Pb = 6 and Fe = 35 ng g\(^{-1}\). Three titanium samples of different purity were analyzed with concentrations in the following ranges: U, Th = <0.007 × 10\(^{-3}\)–0.09, Cd = <0.002–0.7, Cu, Ni, Pb, Cr = 0.01–30 and Fe = 7–6 × 10\(^3\) ng g\(^{-1}\). The IDMS results for one titanium sputter target were compared with those for two different laboratories which showed the urgent necessity for the application of independent and reliable analytical methods.

Multielemental IDA by means of radiometric titration for the determination of Cu and Pb has been discussed.\(^{67}\) A theoretical concept was derived for multielement IDA in a liquid–liquid extraction system. The practical performance was based on radiometric titration. For this purpose, a prototype of a titration/extraction vessel with flow injection was constructed. For calculations of the initial concentrations of the elements of interest from the experimental data, a computer program was developed.

Niobium and tantalum have been quantitatively determined by IDA.\(^{68}\) Preliminary separations of Nb and Ta from each other and from Ti and Zr can be made by precipitation with benzene–selenous acid and extraction with 8-hydroxyquinoline before determination by means of the radioactive isotopes \(^{95}\)Nb and \(^{182}\)Ta. Nb was separated from Zr in 1 M HCl containing 0.5% of citric acid and 1.5% of ammonium selenate and Ta from Zr by increasing the citric acid concentration to 1.5%. Nb was separated from Ta, Zr and Ti by extraction at pH 4.0 to 4.5 with 2% 8-hydroxyquinoline solution in chloroform.

Uranium–plutonium metallic spikes for IDMS accountancy measurements, preparation and characterization have been discussed.\(^{69}\) The advantages were discussed of the use of a solid \(^{235}\)U–\(^{239}\)Pu alloy rather than the conventional \(^{233}\)U–\(^{242}\)Pu solution to provide tracers for the IDMS determination of U and Pu in spent nuclear fuel solutions for reprocessing. The compositions [all percents (w/w)] \(U–0.5\%\) Pu–50% Ti, \(U–0.5\%\) Pu–25% each Nb and Zr and \(U–1.0\%\) Pu–2.3% Nb were chosen on account of their good cold formability, and were prepared by inductive levitation melting, subsequently being cold-rolled to a thickness of approximately 0.1 mm. Metallography of these alloys showed no significant heterogeneity, and \(\gamma\)-ray spectrometry showed that the relative SD of the Pu distribution in portions composed of 0.1 g of U and 1 mg of Pu (the usual added masses) was 0.4% for the U–Pu–Nb–Zr alloy and 0.1–0.2% for the other two.

Sample preparation approaches have been discussed for the IDICPMS certification of reference materials.\(^{70}\) The application of IDA to inductively coupled plasma
mass spectrometry (ICPMS) is discussed. The requirements for accurate sample preparation and instrumental analyte–matrix–plasma interaction for the attainment of precise isotope ratio measurements are presented. The method is illustrated by the determination of Mg, Cd, Mo and Pb in synthetic samples, Cu and Cd in Zn ore and Cu and Mo in sewage sludge. The integration of procedures into the certification program at NIST is described.

Simultaneous radiochemical determination of chemically similar elements by the concentration-dependent distribution method has been described. The method with two substoichiometric systems can be characterized by the following features. The selectivity of the two systems must be different, and desirably each of them should react preferentially with a different element. It is sufficient to use only one tracer for the two systems, but the use of two tracers could be advantageous in some cases. The analysis is based on the fact that if phase distributions in the two systems occur under strictly standard conditions, a set of two distribution ratios corresponds to the two values of the unknown concentrations. The calculation of the unknown concentrations from the two distribution ratios can be carried out using (i) theoretically derived equations based on the equilibria involved, (ii) empirical or semiempirical relationships and (iii) calibration plots. The calibration plots can be used in any case; methods (i) and (ii) can be utilized under conditions required for sufficiently strict validity of the corresponding equations. The method was applied for the determination of Rb and Cs.

The partial isotope separation of U and Fe by means of solvent extraction has been discussed. The separation of isotopes is of great practical importance and, hence, it is worthwhile to explore the possibility of isotope separation by means of the simple method of solvent extraction.

Subst-IDA has been applied for the determination of trace elements in liquid samples, of the carrier content in RI solutions and of concentrations of organic reagents. Cu in mineral acids and in a ZnSe single crystal was determined by substoichiometric extraction with dithizone. Values of 1.8 and 0.018 ppm in nitric acid and of 1.4 and 0.44 ppm in ZnSe were obtained. Cu and P carrier contents in 60Cu and 32P solutions were determined by substoichiometric extractions with dithizone in carbon tetrachloride and with molybdic acid into MIBK in a series of solutions, adding various amounts of Cu and P carrier. An analogous method was applied for the analysis of dithizone and diethylthiocarbamate solutions. The method was also applied to the determination of 60Co radioactivity in environmental samples. The analytical results for water samples are described.

Molybdenum and nickel have been determined in SRMs using the internal normalization technique for high-accuracy IDA. General exact equations and iteration techniques have been developed for internal normalization to eliminate the effect of thermal fractionation on isotope ratio measurements, and therefore IDA, by thermal ionization MS. The techniques were applicable to more than 20 elements, and have been extensively applied to the determination of Mo in ore concentrates (55% Mo) and silicate trace standards (50 and 500 ppm Mo). The SD of all internally corrected Mo isotope ratio measurements was 0.1%. The Mo sample size was 40µg, but the normalization technique should apply to microgram and smaller samples with a more sensitive ion detection system. Procedures are described for the chemical separation of Mo from matrix interferences and for the MS determination of Mo. Application of the techniques to Ni in three pollution SRMs is described.

A new variation of IDA based on double labeling carried out on filter-paper has been described. The determination of microgram and submicrogram amounts of silver (labeled with 110mAg) by precipitation with iodide (labeled with 131I) and of Ca (labeled with 45Ca) by precipitation with phosphate (labeled with 32P) are given as examples. In the first example, the two radioelements (110mAg and 131I) were measured by γ-spectrometry and in the second method (45Ca and 32P) by a β-absorption method. The results show the usefulness of the method.

Coprecipitation has been used as a means of separation in Subst-IDA. It is shown with examples that by applying coprecipitation for separation and by using complexometric and oximetric or reductometric reactions as the substoichiometric reaction, a wide range of complexometric determinations of metal ions (e.g. with EDTA) and many types of redox determinations are opened up for further investigation. The method is simple, not time-consuming and offers many possibilities owing to the freedom to select a suitable precipitate.

A semiquantitative method of isotope dilution in the microgram and submicrogram ranges using the ring oven method has been described. Radioactive tracer elements were added to the sample solution and separated by the ring oven technique. The separated ring of precipitate was counted and the original concentration determined from a calibration graph. Examples are cited for the determination of calcium, iron and phosphate.

Ca and Mg have been determined by isotope dilution at the microgram level. Natural calcium contains 96.97% of 40Ca and 2.06% of 44Ca and the tracer isotope used contained 2.9% of 40Ca and 97% of 44Ca. Precautions were necessary to avoid contamination, e.g. from atmospheric dust and from the vessels used. A solution of known concentration (1 mL) mixed with a known amount of tracer isotope was evaporated under nitrogen to one drop, which was applied to the double Ta filament of the spectrometer and evaporated to dryness.
The residue was covered with ammonium oxalate (as ionization activator) by similar evaporation of three drops of a saturated solution, and the ratio of the two isotopes was determined. Amounts of approximately 1 µg of Ca could be determined readily with a SD of 2.5%. The sensitivity under the conditions used was approximately 0.01 µg. Determination of 10⁻⁴ – 10⁻⁵ µg is considered possible. Interference due to ⁴⁰K can be eliminated by heating the filament to a temperature below that necessary for the determination of Ca. Natural Mg (78.6% of ²⁴Mg and 10.11% of ²⁵Mg) was determined by mixing Mg(NO₃)₂ solution (1 mL) with the tracer isotope (98.5% of ²⁵Mg) and BeO (1 mg) as activator, and applying the concentrated solution to a double rhenium filament. From solutions containing 30.34 and 3.034 µgm L⁻¹ of natural Mg, recoveries were 30.44 ± 0.39 and 3.016 ± 0.086 µgm mL⁻¹, respectively. Under suitable conditions, the measurement of approximately 10⁻⁴ µg was considered possible. Use of a double instead of a single filament increased the sensitivity approximately 100-fold.

Application to the determination of elements and chemical compounds by SI dilution has been reported.²⁹ A review is presented on the use of this technique for the determination of H, rare gases, C, N, O, S, alkali, alkaline earth and heavy metals, the actinium series and compounds containing these elements.

ACKNOWLEDGMENTS

Thanks are due to Dr J.P. Mittal, Director, Chemical Group, BARC and Dr D.D. Sood, Director, Radiochemistry and Isotope Group, BARC for some of the papers on IDA required for this work. Sincere thanks are due to Shri Taher for typing the manuscript in spite of his busy schedule.
